Start: 2/27/2017 3:00:00 PM
End: 2/27/2017 3:45:00 PM
Show Time As: Busy

Good day all,

I am setting up a quick meeting/briefing to go over some the potential issues/questions that we may face regarding the updating of the Perchlorate Occurrence Report that I feel requires Management input. Specifically the Chambers request to remove additional PWSs from our occurrence analysis as well as the inclusion of newer data that has been reported by the California. Attached you will find a briefing that I put together for your review.

Thanks again

Clifton

Subject: RE: Revised Document

Hi Lisa,

We got new information from the MD system. There was some misunderstanding with the information request but here is the latest.

The treatment plant at chapel hill was recently taken off line and it was replaced with new productions wells and treatment plant which started operations in January 27, 2020. Please see the new language that I have incorporated in the revised document below.

"EPA contacted the Chapel Hill System in January 2020. Water system personnel indicated that the Chapel Hill WFP was taken off line and it was replaced with a new treatment plant and five new production wells. The new treatment plant started operations on January 27, 2020. System personnel also indicated that monitoring was conducted in November 2019 and the analysis shows that perchlorate was not detected in either the source well water or the finished water."

Thanks
Sam

Thanks Sam.
Do we know exactly what the contractor asked each PWS? Based on this response: **EPA contacted the Chapel Hill System in January 2020. Water system personnel indicated that no follow-up/updated monitoring data for perchlorate is available.** It appears we only asked about monitoring…did the contractor ask about any changes in source water and/or treatment too?

Thanks,
Lisa

Subject: Revised Perchlorate Briefing Documents

Jennifer:
Attached please find a revised Perchlorate Briefing documents. We had submitted a previous versions of these document for OW review along with the Perchlorate Reductions and Recommendations Documents. We have updated these documents while awaiting further comments from OW. The revisions made to the documents are as follows

- The one pager – Decision for Perchlorate Final Regulatory Action – Has been updated in response to Dave's request to incorporate information about the timing of the release of the stipulation to NRDC regarding the consent decree. This document reflects OGC's input.
- The Reductions Document – has been updated to reflect the information we received from the States of Maryland and Ohio regarding the status of the system that previously detected perchlorate at levels greater than 18ppb. We have also added a document number.
- The Recommendations Document has been updated to reflect add a Document Number.

If OW has not yet reviewed the last versions provided we recommend sending these forward to replace the versions awaiting review. If there are comments on the previous versions we can incorporate those prior to sending them forward.

Hi Pooja,

We are requesting OGC review and clearance of the attached Perchlorate Response to Comment Document. We anticipate that this document will be needed in order to transmit the Withdrawal FRN to OMB. Eric will be reviewing this document concurrently with OGC, and I will let you know if there are any mayor edits as a result of his review.

I have attached a clean version and also a redline version of the document which captures some of your previous comments/edits on the document.

Let me know if you have any questions.

Thank You
Sam

Subject: Draft Responses to Comment - Perchlorate
Attachments: Perchlorate Draft Comment Response Report - Lisa C Review 4-15-20.docx

Hi Lisa,

Attached you will find the remaining sections of the comment response document for Perchlorate. For the other sections, which you had already reviewed, I incorporated your suggested edits as well as those from OGC. But I did not include those sections here because it is easier to navigate the document without those more dense sections.

I am still waiting for ORDs input, but all the other sections are coming together nicely. I will need to finalize the Health Effects section to assemble the document because that section cross-references to all other pertinent sections of the response document.

On this file you will see a few comments that are highlighted yellow because I need to make sure that those are appropriately cross-referenced to the Health Effects section. Once I have your input on this file I should be able to quickly assemble the whole document and I will be able to send the final/draft version to you.

Thanks
Sam

Macara: I understand that WPS are not processing the perchlorate action which is subject to a consent decree deadline because of missing items in the package related to FAR. Since WPS ran the FAR I don't see why this information cannot be added by WPS (note that there is no economic analysis for this final action). It is critical that this action be transmitted to OP ASAP. Thanks for your assistance.

Subject: Important: Perchlorate submittal to OW
Importance: High

Good Morning,

There's some confusion in OW over our submittal of the perchlorate docs. for Charlotte's review. Joe asked that I enter the attached documents into CMS (w/o review) for Charlotte. Is this the formal submittal? To initiate OMB Review, we need to follow the Action Development Process checklist (as applicable) and label the FRN per the attached guidance. (Note: submit the FAR memo and associated concurrences in on PDF file.)

Thanks for your timely attention…any questions, please let me know, thanks!

Attachments: Draft Responses - Health Effects Comments.docx

Hi Lisa,

Here are the draft responses to the health effects comments. I will update responses and check for consistency as soon as we get feedback from ORD. I also sent this document to Greg Miller for his awareness. He told me that he would look at the responses and get back to us if needed.

Thanks
Sam

Hi Eric, please see attached document. It incorporates your suggested edits and addresses your questions.

I am also waiting for some additional feedback form OSWER on the table they provided, as they way it reads now it appears to show several entries for the same mitigation site. Depending on their feedback we might have to update that table.

Thanks
Sam

Hi Rajiv,

Here is OGCs input regarding the responses to the HRRCA comments. As you will see in their comments it looks like there is a misunderstanding of the process we are taking in informing the withdrawal. We might have to have a call with them in the coming days to have a discussion about how we have done this in the past and how we do not want to set a precedent on involving economic considerations into the Reg Det process.

Thanks
Sam

Hi Sam –

Apologies but I've been caught up on other matters and haven't had a chance to finish reviewing the Economic Assessment Responses to Comments. I will aim to get comments to you tomorrow.

Thanks for responding to the legal comment responses; I'm currently checking with Carrie to see whether the response re the MCLG is sufficiently responsive to the comment as drafted – or whether we need to address it more specifically (she was the one who had initially flagged this one as requiring a response).

Jennifer:

Attached for transmission to OW are revised versions of the FRN for the Perchlorate Final Action. There is both a clean and track changes version that includes edits made since initiating FAR (including the edits you asked for on Saturday and adding 3 more SAB recommendations to page 14 that were in the proposal but were not included in the draft we provided you on Friday). Also please find clean version of the transmittal memo from you to Dave Ross and the Action memo incorporating your edits.

Please note that there is also a redline version of the Action Memo for you to see the responses to your comments on the document. I do not recommend transmitting that memo to OW.

Hi Eric,

Here is a revised Redline of the document (from FAR). We had a few questions/issues for your consideration about the attached file. Specifically:,

1- Page #1, Notice Tittle: We did not accept the edits to the notice tittle. Because, the tittle of the notice was specifically crafted by OGC to capture the multiple actions EPA is taking. Suggest consulting with OGC before modifying this tittle.
2- Page #14, SAB Recommendations: SAB provided 4 main recommendations in 2013 but we only listed the first recommendation. Please advise if we should list all 4 recommendations here or not.
3- Page #26, Missing HRRCA Text: This language was offered by TAB in its 5-13-20 version of the draft FRN, but it did not show up in the version provided by OGWDW with Eric's & Jennifer's comments. We have inserted the language here for the reviewer's consideration. Please advise if we should keep it.

Once you provide your feedback, I will modify the redline version and also provide a Clean copy for transmittal.

Thanks
Sam

Jennifer

Attached for your approval and transmittal to the Office of Water for their approval and transmittal to the Office Policy for initiation of interagency review is a *Federal Register* notice titled: "Notice of Final Action on Perchlorate." Also attached for your review are a draft transmittal memo from you to the Assistant Administrator of Water, a draft Action Memorandum and a track changes version of the FR notice that denotes the changes made as a result of Final Agency Review.

On February 11, 2011, the EPA published a determination to regulate perchlorate in drinking water (76 FR 7762). On June 26, 2019 (84 FR 30524), the EPA published the proposed National Primary Drinking Water Regulation for Perchlorate and requested public comments on multiple alternative actions, including withdrawing the 2011 determination to regulate perchlorate. The EPA received approximately 1,500 comments on the proposed rule. In the attached notice, the EPA is withdrawing the 2011 Regulatory

Determination and is making a final determination not to regulate perchlorate based on the Agency's consideration of public comments and the best available information.

I recommend that you approve and transmit the attached notice to the Office of Water for their review, approval and transmission to the Office of Policy to initiate interagency review in accordance with Executive Order 12866. If you need additional information or have questions pertaining to any aspect of this notice, please call me or have your staff contact Samuel Hernandez at 202-564-1735.

Jennifer: Attached please find clean copies of the recommendations and reductions documents for perchlorate. We have incorporated your edits. Please note with respect to your question about CCR reporting of perchlorate monitoring

CCR regulations under 141.153.(d)(1) requires the CCR include data on detected contaminants subject to mandatory monitoring including

i. Contaminants subject to an MCL, action level, MRDL or TT
ii. Contaminants for which monitoring is required under the UCMR
iii. Disinfection byproducts or micriobial contaminants for which monitoring is required.

Subject: RE: Revised Document

Thank you Eric & Lisa – The attached contain a very few edits/comments. And then, these are ready to go to OW for review. Regarding the outreach plan, continue to pursue the discussions with ASDWA and AWWA as we discussed and agreed to with Dave. However, I'm not sure that we can say these reports will be released soon, maybe it is better to say that there is the potential for them to be issued in the near term.

Thanks much,
Jennifer

Hi Lisa,

We got new information from the MD system. There was some misunderstanding with the information request but here is the latest.

The treatment plant at chapel hill was recently taken off line and it was replaced with new productions wells and treatment plant which started operations in January 27, 2020. Please see the new language that I have incorporated in the revised document below.

"EPA contacted the Chapel Hill System in January 2020. Water system personnel indicated that the Chapel Hill WFP was taken off line and it was replaced with a new treatment plant and five new production wells. The new treatment plant started operations on January 27, 2020. System personnel also indicated that monitoring was conducted in November 2019 and the analysis shows that perchlorate was not detected in either the source well water or the finished water."

Thanks
Sam

Thanks Sam.
Do we know exactly what the contractor asked each PWS? Based on this response: **EPA contacted the Chapel Hill System in January 2020. Water system personnel indicated that no follow-up/updated monitoring data for perchlorate is available.** It appears we only asked about monitoring…did the contractor ask about any changes in source water and/or treatment too?

Thanks,
Lisa

Hi Lisa,

I sent a revised draft version of the briefing document to Eric earlier this week. We are waiting for additional input that OGC will provide to us. Here is the revised document, as reviewed by Lisa, that I shared with Eric. If you have additional information, I will be glad to incorporate into the document.

I will be in the office tomorrow morning if you want to hand those notes to me, or you can also email them.

Thanks
Sam

Subject: Perchlorate briefing

Sam,
I just had a conversation with Eric. He said the meeting with with Dave Ross and the Administrator has been delayed however he said we need to put together the briefing materials ASAP. He gave me a brief summary of the 3 options to reflect based on direction from last week. I can email you those point but thought you might have in your notes. He had one addition that is for the option recommending a MCL we should specify that value would be 18. Have you been working on preparing materials? Eric was hoping to have them by tomorrow for his review. Please let me know. I'm out of the office for an appt. but will follow up via email shortly.

Lisa

Subject: Response to comment document
Attachments: Draft Responses Section 8 - Health Effects 4-24-20 v1.docx; Consolidated Perchlorate Draft Comment Response Report 4-24-20 v1.docx

Hi Lisa,

Attached you will find the consolidated response to comment document. To make the review process easier in this stage, I decided to have a separate file that includes only Section 8 (Health Effects). I think it is easier this way because it is the largest section in the document and providing edits and comments on the lager document might impact the editorial format on other sections.

I have only received partial input from ORD, I told Lynn that I could not wait any longer for their input and that I would send the document forward for review and that I was leaving placeholders for their input. There are only a handful of comments pending. She is aware of our very aggressive schedule on perchlorate.

I will be working in the coming days with the team to make another QA of the document to make sure that any issues we find are captured in the next round of revisions. I am also working on the cover and front matter of the report.

Thank You
Sam

Subject: RE: draft summary of perchlorate public comments

Thanks Lisa this breakdown is helpful but it pointed out to me that the 109 extensive and substantive letters don't all appear to be summarized.

I think there isn't a need to organize the commenters by organization type and there are some groups that are hard to categorize (i.e. we have ACWA as a regulated stakeholder but AWWA is a trade organization when the both represent drinking water utilities) I also think there is redundancy in the summary of the comments that I tried to eliminate in the attached.
Can the team take a look and see if there are organizations that have submitted extensive and substantive comments that we have not listed and if so please list them in the categories of support that are in the attached.

Subject: RE: draft summary of perchlorate public comments

Hi Lisa,

Here is a revised version which incorporates previously suggested edits.

- We received 6 comment letters in support of the proposed rule at 56 ppb.
- I cannot categorically confirm that the mass mailing campaign was organized by any group, so I am removing that designation from the summary document.
- From the individual substantive letters
    - 1 supports withdrawal option
    - 1 supports 90 ppb option
    - 6 support 18 ppb option
    - 23 support regulation at a stricter level than 18pbb

Thanks
Sam

Jennifer

Attached for your approval and transmittal to the Office of Water for their approval and transmittal to the Office Policy for initiation of interagency review is a *Federal Register* notice titled: "Notice of Final Action on Perchlorate." Also attached for your review are a draft transmittal memo from you to the Assistant Administrator of Water, a draft Action Memorandum and a track changes version of the FR notice that denotes the changes made as a result of Final Agency Review.

On February 11, 2011, the EPA published a determination to regulate perchlorate in drinking water (76 FR 7762). On June 26, 2019 (84 FR 30524), the EPA published the proposed National Primary Drinking Water Regulation for Perchlorate and requested public comments on multiple alternative actions, including withdrawing the 2011 determination to regulate perchlorate. The EPA received approximately 1,500 comments on the proposed rule. In the attached notice, the EPA is withdrawing the 2011 Regulatory Determination and is making a final determination not to regulate perchlorate based on the Agency's consideration of public comments and the best available information.

I recommend that you approve and transmit the attached notice to the Office of Water for their review, approval and transmission to the Office of Policy to initiate interagency review in accordance with Executive Order 12866. If you need additional information or have questions pertaining to any aspect of this notice, please call me or have your staff contact Samuel Hernandez at 202-564-1735.

Thank you all for pulling this information together so quickly. The attached includes a number of comments, primarily around whether we have more information. I recognize that there are probably many instances where we just don't have anything else but I think there are a few places where we could find additional information. I'm happy to discuss.

Jennifer

Subject: RE: FOR REVIEW: Perchlorate Reductions

Jennifer,
Attached is the second document requested during option selection. There are 5 PWSs of the 15 we identified as having UCMR1 results >18ppb that have not responded to our request for updated information. They are highlighted in yellow. We will continue to try, but I wanted to get this to you sooner rather than later.
Let us know if you have questions, concerns or need additional information.
Lisa

Subject: FOR REVIEW: Perchlorate Recommendations for PWSs

Jennifer,
During option selection on 1/9 with Administrator Wheeler, he requested OGWDW prepare two documents:

1. Recommendations for PWSs that may be concerned about perchlorate in drinking water (attached)
2. Reductions in perchlorate levels and actions to reduce levels since UCMR1 (pending)

For your review is document #1, which incorporates edits from Eric and Christina. We are working on document #2 and should have a draft for your review soon.

Let us know if you have questions, concerns or need additional information.
Lisa

Lisa:
I received comments from Jennifer on the perchlorate briefing and the attached reflects those comments. The most significant ask is to present the total population vs protected population breakdown as shown on page 4. Let me know if you have any concerns or if it is not possible to make the requested changes before noon on Monday. Thanks

Subject: Post-closing docket update

Hi Sam,

Below is an update to the perchlorate docket with public comments posted as of this morning. Given that the docket closed yesterday, there will likely be more comments posted over the coming days, and we will keep you updated.

Of the 59 comments posted by the docket so far, the following were submitted by commenters other than the general public – copies of the letters are attached:

1. Salt River Pima-Maricopa Indian Community (SRPMIC) et al. (Doc. #0158)
2. Water Resources Department, Tohono O'odham Nation (Doc. #0161)
3. El Paso Water (Doc. #0169)
4. Massachusetts Department of Environmental Protection (MassDEP) (Doc. #0236)
5. Association of Metropolitan Agencies (AMWA) (Doc. #0239)
6. Metropolitan Water District of Southern California (Doc. #0241)
7. Division of Scientific Programs, California Office of Environmental Health Hazard Assessment (OEHHA) (Doc. #0242)
8. Innovative Water Care, LLC (Doc. #0243)
9. Environmental Protection Network (EPN) (Doc. #0247)
10. Association of State Drinking Water Administrators (ASDWA) (Doc. #0248)
11. Natural Resources Defense Council (NRDC) (Doc. #0249, and its two attachments 0249.1 and 0249.2)

We anticipate there will be at least once mass mailing campaign, but have not seen any officially posted by the docket yet.

In terms of numbers, please note that:

- The comment count on regulations.gov is 1,280, only 59 of which have been posted so far.
- As far as we can determine, the docket has "parked" about 1,400 letters for further evaluation, and we anticipate that most of those will be modified mass mailers.
- There are also another 20 or so pending various levels of docket review.
- Comment numbers at this time are in draft form (hence why they don't add up), but hopefully this gives you a better sense of what is coming.

Please let us know if you have any questions about the above, or would like additional information.
Kind regards,
Geraldine

SALT RIVER

PIMA-MARICOPA INDIAN COMMUNITY

10005 East Osborn Road / Scottsdale, Arizona 85256

The Salt River Pima-Maricopa Indian Community's (SRPMIC or Community) Community Development Department's (CDD) Environmental Protection and Natural Resources (EPNR) Division in conjunction with the SRPMIC Office of the General Counsel (OGC) have reviewed the information on the proposed National Primary Drinking Water Regulation (NPDWR) for perchlorate in order to establish a Maximum Contaminant Level (MCL) and a health-based Maximum Contaminant Level Goal (MCLG) at 56 micrograms per liter. SRPMIC staff disagrees with the proposed 56 micrograms per liter and our comments and questions are below in regards to the three alternative regulatory options.

- An MCL and MCLG for perchlorate set at 18 micrograms per liter.

While an MCL of 18 micrograms per liter may be attainable for most Public Drinking Water Systems, it does not make that a safe number. If a recommendation must be made, then this number may be tentatively acceptable for now until additional, more thorough, scientific investigations are completed. There are numerous states that have already adopted lower limits (e.g. California 6 micrograms per liter MCL, and Iowa 4.9 micrograms per liter), and have done so while taking into consideration the multiple sources of perchlorate in which the public are exposed. The studies completed (according to EPA June 12, 2019 online PPT presentation "National Primary Drinking Water Regulation for Perchlorate: Proposed Rule" and Section III of the proposed rule document), arrive at the proposed numbers, but do not account for contaminated food (Jackson W.A., Joseph P., Laxman P., Tan K., Smith P.N., and Yu L., et al. Perchlorate accumulation in forage and edible vegetation. *J Agric Food Chem* 2005: 53: 369–373.), soil, air, and occupational exposure (unless it is unclear).

The Community questions whether the studies that EPA used to determine their proposed levels are accurate or sufficient enough to arrive at a "real, health-based" decision considering the disparity between the proposed numbers and some state numbers. Methodology and data from states with adopted levels should have been considered in EPA's decision, as should have studies on animals, and in people with thyroid problems.

Have there been any peer-reviewed, published studies on perchlorate using animals? If not, can resources be gathered from different sources (research institutions, federal agencies, etc.) to conduct these types of studies in order to

arrive at a more defensible "health-based" number? These tests would need to examine different exposure levels over time, and consider multiple age groups (not just based on interviews and surveys). Are studies currently being initiated on people with thyroid problems that reside in areas close to sources of perchlorate contamination? Can studies be done to follow the medical history of patients that, as of now, are found to have high levels of perchlorate in urine, in order to learn more about thyroid disruption, other possible health effects, and continuous long-term exposure, etc. (similar to "Perchlorate Exposure of the US Population, 2001-2002" from the Journal of Exposure Science and Environmental Epidemiology)? Can funds also be used to research the presence and effects of perchlorate in infants and children below the age of 6 years old? Did EPA look at the FDA's "Exploratory Survey Data on Perchlorate in Food 2004-2005" in its determination of a "health-based" level?

- An MCL and MCLG for perchlorate set at 56 or 90 micrograms per liter.

  A proposed MCL of 56 or 90 micrograms per liter has a large disparity from a number of state standards and proposed state standards (e.g. California, Massachusetts, Vermont, Maryland, and Arizona's Regional Screening Level). It would therefore be absurd to set an MCL and MCLG this high for perchlorate when states have already determined that their public water systems are able to clean to a safer level.

- Withdrawal of the Agency's 2011 determination to regulate perchlorate in drinking water, which was a reversal of the 2008 preliminary determination to not regulate perchlorate.

  Withdrawal of regulation will only encourage the industry to abandon any preventative measures to contain current contamination. Withdrawal will allow the industry to continue to manage their waste on a case by case basis.

  The Community, and similarly, other Tribal nations, rely on the EPA requirements and standards to support our efforts to keep Tribal waters safe from environmental health hazards. The agency's guidance/regulation may also help Tribal nations enforce possible contamination in the absence of existing local environmental rules and regulations (which could take some years to achieve). Native American communities already have a higher diabetes prevalence, according to "Traditions and Diabetes Prevention: A Healthy Path for Native Americans" from the American Diabetes Association. Having diabetes prevalence and possible exposure to perchlorate, which affects the thyroid, would only place the Community at a higher health disadvantage. Furthermore, Native American communities may not always have the resources to provide proper medical assistance, and already experience environmental injustice (equaling greater negative effects from contamination) based on where reservations are located. In conclusion, it is in the best interest of the Community and its members to expect and follow the most stringent and protective drinking water regulations in order to protect a health-wise vulnerable population.

Standards and Risk Management Division
Environmental Protection Agency

These comments address the US Environmental Protection Agency (EPA) proposed National Primary Drinking Water Regulation for perchlorate to establish a Maximum Contaminant Level (MCL) and a health-based Maximum Contaminant Level Goal (MCLG) at 56 micrograms per liter (µg/l) (May 23, 2019). The current Interim Drinking Water Health Advisory level for perchlorate is 15 µg/l. The EPA refused to use all its scientific evidence that perchlorate (a neurotoxin) can affect neurodevelopment and intelligence quotient (IQ) in children[1]. This scientific information may have produced a proposed MCL and MCLG lower than 15 µg/l. The EPA's new proposed rule of 56 µg/l does not provide adequately protection to unborn children in the first trimester of pregnancy.

The EPA is seeking comments on three alternative regulatory options in its new proposed rule[2]:

1. An MCL and MCLG for perchlorate set at 18 micrograms per liter.
2. An MCL and MCLG for perchlorate set at 90 micrograms per liter.
3. Withdrawal of the agency's 2011 determination to regulate perchlorate in drinking water.

Prior to the new proposed rule of 56 µg/l, many environmental scientists believed that the EPA was moving towards protecting a mother's perchlorate exposure in the first trimester from fetal harm[3].

The EPA abruptly changed course by altering its decision in three significant ways[3]:

1. Rejecting five epidemiology studies showing harm at even lower exposure levels in favor of one IQ study [3,4].
2. Choosing an MCL that allows an IQ loss of 2 points even though the study showed a 1 point loss was statistically significant.
3. Dismissing an alternative, population-based method that the EPA (2017) once supported that reinforces the need for a more protective standard.

The Tohono O'odham Nation Water Resources Department (Department) believes that EPA's refusal to use all of its scientific evidence and its proposed MCL and MCLG of 56 µg/l lessens the Safe Drinking Water Act's ability to protect the public, especially the unborn and newborn, from adverse effects[3,5].

The Department believes the EPA is required to protect children from any harm to their brain development from perchlorate exposure during the first trimester; it is their duty and responsibility. The Department also believes the EPA's negligence in using one study to help deregulate parts of the Safe Drinking Water Act in favor of industry is not fair and reckless to the long term health of all Americans.

The true test for whether any MCL for perchlorate is safe will always be: If it was your wife and our unborn child being exposed, would you feel confident in giving them water with any amount of perchlorate.

The Department supports a perchlorate MCL and MCLG lower than the current 15 µg/l.

Respectfully yours,

Selso Villegas

el paso WATER

August 2, 2019

The Honorable Andrew Wheeler
Administrator
Environmental Protection Agency
1200 Pennsylvania Avenue, N.W.
Washington, D.C. 20460

Dear Mr. Wheeler:

I want to thank you for the opportunity to comment on the Environmental Protection Agency's proposed rulemaking on perchlorate levels in drinking water. From our perspective, opportunities such as this are highly valuable in allowing public water utilities to contribute in a meaningful way to the development of sound policy that protects public drinking water resources.

Based on the EPA's chosen neurodevelopmental endpoints and the occurrence of perchlorate at the three given MCLs/MCLGs in drinking water systems, El Paso Water agrees with the EPA's determination that due to the low occurrence of perchlorate nationwide, this particular proposal does not present a meaningful opportunity for health risk reduction as is laid out in the Safe Drinking Water Act (SDWA).

In short, we believe this to be a solution in search of a problem. With national detection levels at less than two percent (and readings for the majority of tests were well below these thresholds), the frequency of occurrence is simply not sufficient to impose a regulatory burden on the vast majority of public water systems, including our own at El Paso Water.

In our own experience in El Paso, Texas, we have reviewed sampling records dating back to 2005. Of more than 750 samples for perchlorate, we had only one detection, which was at 17 micrograms per liter, far below the proposed regulatory levels. It was determined that this was naturally occurring perchlorate, yet because of this determination, additional sampling would be required across the system despite the single finding. While we currently have the in-house instrumentation to monitor for perchlorate, there is a cost attached for each time the sample goes through laboratory analysis, which is substantial at $25 per sample multiplied by 50 wells times the frequency of sampling

Even though our one reading was far below regulatory threshold, depending on the nature of the regulations put in place, Granular Activated Carbon (GAC) filtration might be required at the one well that produced the detection. At an estimated cost of $200,000 for the installation of a GAC filtration vessel, it may be more advantageous to abandon the well altogether.

EPWater also agrees with the EPA's statement on the cost-benefit analysis that, based on the parameters laid out by EPA and SDWA, the benefits do not justify the costs. We believe that our limited resources are better used elsewhere.

We support the EPA's efforts to continue periodic monitoring, research and modeling – especially in targeted areas with high detections of perchlorate to understand causes and provide guidance to states on any increasing levels that may warrant further evaluation of any public health impacts.

Uploaded through www.regulations.gov; **Docket ID No. EPA-HQ-OW-2018-0780.**
Comments Regarding National Primary Drinking Water Regulation for Perchlorate

The Massachusetts Department of Environmental Protection (MassDEP) appreciates the opportunity to comment on the United State Environmental Protection Agency's (USEPA) federal register notice entitled National Primary Drinking Water Regulations: Perchlorate: A Proposed Rule, Docket ID No. EPA-HQ-OW-2018-0780.

Perchlorate has been a priority drinking water contaminant issue for MassDEP for over a decade. In 2006 MassDEP adopted a drinking water standard or maximum contaminant level (MCL) of 2 micrograms per liter (ug/L) for perchlorate. This MCL was promulgated to address perchlorate toxicity to the developing fetal and infant brain. MassDEP has successfully implemented this standard since that time.

After nearly 21 years of assessment, USEPA is recommending a national MCL of 56 ug/L for perchlorate. This proposed limit is based on the output of a complex and uncertain computer model, and accepts an IQ loss of 2% among those exposed to perchlorate at this level. USEPA has requested comment on whether the target of acceptable IQ loss should instead be based on a 1% or 3% IQ loss, or whether the agency should conclude that no standard is warranted.

MassDEP disagrees with all of these options. Perchlorate has been shown to disrupt thyroid function through at least one mechanism of action involving inhibition of iodide uptake in the thyroid. Extensive human data demonstrates that chemical and physiological conditions that disrupt normal thyroid function can cause a range of adverse health effects. The developing neurological system in the fetus and infants is particularly sensitive to thyroid disruption. Considerable evidence from laboratory

experiments on animals and human epidemiological studies have reported perchlorate effects on the thyroid and on measures of neurological development.

MassDEP is alarmed that USEPA would consider a 2% or 3% IQ decrement, attributable to exposure of the fetus to a *single* contaminant in drinking water, as an acceptable health based target. Of the options presented, a 1% IQ decrement should be the maximum considered, which would be consistent with USEPA guidance, and which is also noted in the Federal Register Notice. The notice states that "(a) BMR [benchmark response] of 1% has typically been used for quantal human data from epidemiology studies". To our knowledge there is no regulatory precedent for determining that the IQ effect levels of 2-3% are acceptable. Indeed this policy decision is inconsistent with conclusions of the USEPA's Clean Air Scientific Advisory Committee (CASAC) in its consideration of the National Ambient Air Quality Standard (NAAQS) for lead, another neurotoxin, and with an assessment completed by the California Office of Environmental and Human Health Assessment (OEHHA) regarding lead in drinking water. Specifically, USEPA's CASAC concluded that a "population loss of 1-2 IQ points is highly significant from a public health perspective" (https://www.epa.gov/sites/production/files/2016-03/documents/finalrule_20081015presentation.pdf). Similarly, OEHHA chose a change of 1 IQ point as a benchmark target in a derivation of a health guidance value for lead in drinking water for use in health risk assessments at school sites.

MassDEP also wishes to emphasize a point appropriately noted in USEPA's documentation, that IQ is an incomplete measure of neurotoxicity and does not reflect other adverse outcomes, including various behavioral effects, associated with perchlorate exposure. These adverse outcomes can have highly significant impacts on individuals and society. This concern is reinforced in the USEPA Federal Register notice in Table III-2, which lists measures of neurological effects that are more sensitive to perchlorate than IQ. Some of the other effects associated with thyroid hormone deficits, as noted by USEPA in the Federal Register Notice, include ADHD, autism, and delayed cognitive development, among others. These end points represent significant potential for compromised health outcomes and negative public health measures that should be more robustly addressed.

USEPA has derived three alternative toxicity values (reference doses or RfDs) for perchlorate based on "acceptable" modeled IQ losses of 1, 2 or 3%. RfDs are an estimate of a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime.

In its discussion of the proposed RfD options in the Federal Register, USEPA acknowledges numerous uncertainties inherent in its derivation of these values. These uncertainties are attributable to the many limitations of the complex biologically based dose response (BBDR) model used, and deficiencies in the data USEPA relied upon to predict perchlorate IQ loss. While MassDEP acknowledges that the BBDR model represents an advance that will help scientists better understand thyroid function and the potential effects of thyroid toxicants, it should be considered an experimental research tool with uncertain predictive utility. Some of the uncertainties in the model and the overall database are identified by USEPA in the Federal Register notice. The uncertainties USEPA identifies include:

1) **Relationship between exposure and outcome** ("uncertainty in the relationship between perchlorate exposure and subsequent neurodevelopmental outcomes");
2) **Limited toxicokinetic calibration data** ("very few toxicokinetic calibration data are available for the perchlorate to thyroid hormone relationship described in the BBDR model");
3) **Incomplete understanding of iodine depletion / intake levels and TSH compensation** ("aspects such as competitive inhibition at the sodium / iodide symporter (NIS), depletion of iodide stores under different iodine intake levels and physiological states, and the ability of the Thyroid Stimulating Hormone (TSH) feedback loop to compensate for perturbations in thyroid function each have their own uncertain features");
4) **Incomplete understanding of maternal** free Thyroxine **(fT4) level impacts on IQ and several factors impacting this relationship** ("uncertainties linking maternal fT4 levels to offspring IQ....(which) include the population for which dose-response information is available (i.e., no study is U.S. based), a lack of study information on the iodine intake status for the population for which the dose-response information is available, uncertainties around the methods used to assess maternal fT4 measurement during pregnancy, and uncertainties related to the true distribution of fT4 for a given iodine intake";
5) **Incomplete understanding of infant thyroid levels and outcomes** (".....some uncertainty due to the lack of information linking incremental changes in infant thyroid hormone levels to adverse neurodevelopmental outcomes");
6) **Incomplete understanding of fetal thyroid development after the first trimester** ("this analysis is assuming that protecting a first trimester fetus from alterations in maternal fT4 will protect the fetus throughout pregnancy" and "there is some uncertainty about the impact perchlorate may have on the fetal thyroid gland, and subsequent neurodevelopmental impacts, in later trimesters of pregnancy").

Although USEPA's materials present a daunting compilation of uncertainties, its list is not complete. USEPA's approach does not adequately account for data gaps relating to other potentially more sensitive effects. Neither does USEPA's approach address the fundamental uncertainty regarding perchlorate's mode of action, which may involve additional mechanisms such as effects on organification and thyroid hormone transport, in addition to competitive inhibition at the sodium iodide symporter (NIS).

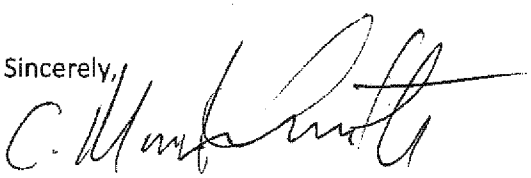
Toxicologists generally account for uncertainties such as these by applying uncertainty factors (UFs) in the derivation of RfDs. By convention and USEPA guidance, an UF of either 3 or 10 is applied to account for uncertainty in sensitivities and another factor of 3 or 10 to account for data gaps that might lead to an underestimate of effects. Despite the extensive list of highly significant uncertainties noted above, the USEPA applied a total UF of only 3 in its RfD derivations claiming this as sufficient to "account for the uncertainties in modeling the impacts of perchlorate ingestion on the thyroid hormone levels for pregnant mothers with low iodide intake, and the uncertainties in predicting the neurodevelopmental effects of these thyroid hormone changes on their children". MassDEP does not agree that this is sufficient. Given the range of USEPA's acknowledged uncertainties in multiple areas, as well as

additional uncertainties not addressed related to perchlorate's mode of action, an UF of 10 should be the minimum value applied and a factor of 30 could easily be justified.

If an UF of 10 is used with the USEPA proposed allowable IQ loss of 1%, a revised RfD of 0.31 ug/kg-day results. USEPA's perchlorate intake from food, derived as described in the Federal Register Notice, equals 0.45 ug/kg-day. This exceeds the more appropriate RfD alternative derived above (0.31 ug/kg-day). Using the more appropriate RfD of 0.31ug/kg-day and the USEPA default relative source contribution (RSC) factor (the fraction of the RfD allowed to come from drinking water) of 20% to derive an appropriate drinking water value, the result equals 1.9 ug/L. This value is much lower that the proposed MCL, and is close to the maximum contaminant level adopted by and implemented in Massachusetts.

In conclusion, MassDEP does not support USEPA's proposed options for addressing perchlorate in drinking water, which are likely to allow for significant adverse public health impacts. An MCL should be based on an assessment that fully addresses perchlorate's toxicity and uses appropriate, health protective uncertainty factors in its derivation. MassDEP urges the Agency to revise its proposal as suggested.

Sincerely,



C. Mark Smith Ph.D., M.S.

Director
Office of Research and Standards

c.mark.smith@state.ma.us

THE METROPOLITAN WATER DISTRICT
OF SOUTHERN CALIFORNIA

Office of the General Manager

August 23, 2019

Mr. Samuel Hernandez
Office of Ground Water and Drinking Water
Standards and Risk Management Division (Mail Code 4607M)
Environmental Protection Agency
1200 Pennsylvania Avenue NW
Washington, DC 20460

Dear Mr. Hernandez:

Comments on Docket ID No. EPA-HQ-OW-2018-0780, Proposed National Primary Drinking Water Regulation for Perchlorate

The Metropolitan Water District of Southern California (Metropolitan) appreciates this opportunity to comment on the U.S. Environmental Protection Agency's (EPA) proposed National Primary Drinking Water Regulation for perchlorate (84 Fed. Reg. 30524 (June 26, 2019), corrected 84 Fed. Reg. 33045 (July 11, 2019)). Metropolitan is a regional water wholesaler whose primary purpose is to provide its 26 member agencies with a safe and reliable water supply. Metropolitan imports water from the Colorado River, as well as from the State Water Project, and delivers it to its member agencies, which in turn directly or through their sub-agencies provide water to approximately 19 million people in Southern California. The lower Colorado River is a major drinking water source for not only Southern California, but also Arizona, Nevada, and northern Mexico.

Metropolitan disagrees with the fundamental assumptions that underlie EPA's proposed National Primary Drinking Water Regulation for perchlorate. Under the Safe Drinking Water Act, EPA should establish maximum contaminant levels (MCLs) for those contaminants that: 1) may have an adverse effect on public health, 2) are known to or likely to occur at levels of public health concern, and 3) in the sole judgment of EPA, regulation of the contaminant presents a meaningful opportunity for health risk reductions for persons served by public water systems. In this regard, Metropolitan offers the following comments:

1. Metropolitan recommends that, in setting an MCL for perchlorate, EPA consider the health effects data used for setting the MCLs and Advisory Levels for perchlorate by several states, as well as the rationale for setting those standards.
2. Metropolitan has concerns with EPA's underlying assumptions and analysis of national occurrence data for perchlorate. First, EPA does not have an up-to-date accounting of perchlorate contamination, either as a drinking water contaminant or from cleanup activities. Second, EPA excluded perchlorate data from California and Massachusetts which led to EPA's proposed 18 µg/L, 56 µg/L, or 90 µg/L MCL levels. Metropolitan recommends that EPA reanalyze national occurrence data for perchlorate, including data from California and Massachusetts.

Since the late 1990s, Metropolitan has been working to address perchlorate contamination of the Colorado River. In September 2009, Metropolitan submitted comments on the Perchlorate Supplemental Request for Comments (74 Fed. Reg. 41883 (Aug. 19, 2009)), emphasizing that a determination by EPA to regulate perchlorate in drinking water would help support cleanup efforts along the Colorado River and other contaminated sites. We continue to urge EPA to establish a drinking water regulation for perchlorate that is protective of human health and prevents any adverse impact to the Colorado River and the millions of users that rely upon it as a source of drinking water supply. As such, Metropolitan offers the following comments:

3. Metropolitan asks EPA to establish a drinking water standard for perchlorate that supports the ongoing remediation efforts and target cleanup goals at two chemical manufacturing facilities near Henderson, Nevada. Metropolitan, along with the Central Arizona Project (CAP), Southern Nevada Water Authority (SNWA), and the Nevada Division of Environmental Protection (NDEP), have been working cooperatively with EPA to address this long-standing issue, and the continuation of remediation at these sites is of paramount importance to the drinking water quality for the southwestern United States.
4. Metropolitan urges EPA not to withdraw its February 11, 2011, determination to regulate perchlorate in drinking water. If EPA withdraws its intent to regulate perchlorate, drinking water utilities in Nevada and Arizona which rely on Colorado River water could then have higher levels of perchlorate in their source water. The impact on California drinking water utilities would be even more significant because they may not be able to comply with California's existing maximum contaminant level (MCL) for perchlorate of 6 micrograms per liter (µg/L) and could be exposed to additional litigation and potential liability.

These four comments are described in further detail below.

1. **Metropolitan recommends that, in setting an MCL for perchlorate, EPA consider the health risk assessment process used by other states such as California in establishing MCLs and Advisory Levels for perchlorate. Metropolitan also recommends that EPA consider the monitoring and compliance guidance provided by California and Massachusetts in the development of their respective perchlorate drinking water regulations.**

California's MCL for perchlorate is 6 µg/L, effective October 2007. California's MCL for perchlorate is based on perchlorate's health risks, its detectability and treatability, and the cost of treatment. (Cal. Health & Safety Code § 116365(a), (b).) Thus, California considered many of the same factors that EPA is analyzing. Metropolitan encourages EPA to review the agency documents supporting California's MCL and Public Health Goal (PHG) for perchlorate, including the California Office of Environmental Health Hazard Assessment's (OEHHA) *Final Technical Support Document for Perchlorate in Drinking Water* (Feb. 2015) [1] and California Department of Public Health's (DPH) *Final Statement of Reasons, Perchlorate Primary Maximum Contaminant Level (MCL), Title 22, California Code of Regulations* (June 25, 2007)[2].

In setting the MCL for perchlorate, California found that the occurrence data indicated both a significant level of drinking water contamination and a potential for adverse health effects."[3] In February 2015, OEHHA lowered the PHG for perchlorate from 6 µg/L to 1 µg/L based on new research that focused on the effects of perchlorate on infants. The purpose of the reduced PHG of 1 µg/L is "to identify a level of perchlorate in drinking water that prevents perchlorate-related reductions in thyroidal iodide uptake and subsequent decreases in thyroid hormone production that may be associated with any of these adverse health effects." (OEHHA, *Final Technical Support Document for Perchlorate in Drinking Water* (Feb. 2015) at p. 158.) California Health and Safety Code Section 116365(a) requires the California State Water Resources Control Board (State Water Board) to set a primary drinking water standard for perchlorate that is as close to the PHG as is economically and technologically feasible.

As a result, on July 5, 2017, the Division of Drinking Water (DDW) recommended a two-step approach for possibly revising California's perchlorate MCL. First, DDW would lower the DLR from the current 4 µg/L concentration to a level closer to, equal to, or less than the PHG of 1 µg/L. With a revised DLR, new occurrence data can be collected to support the development of a revised MCL, if appropriate. Second, if supported by the new occurrence data, DDW would propose a new MCL as close to the 1 µg/L PHG as is technologically and economically feasible. The State Water Board approved DDW's proposal, and DDW is currently exploring the feasibility of establishing a lower DLR for perchlorate which might then result in a new, lower MCL for perchlorate of 1 µg/L or a level close to 1 µg/L.

Similarly, Massachusetts set an MCL for perchlorate of 2 µg/L in 2006. The chart below, which is adapted from OEHHA's *Final Technical Support Document for Perchlorate in Drinking Water*

---

[3] DPH, *Final Statement of Reasons, Perchlorate Primary Maximum Contaminant Level (MCL), Title 22, California Code of Regulations* (June 25, 2007) at p. 4.

(Feb. 2015) at page 156[4], shows the MCLs for California and Massachusetts and the Advisory Levels for other states with standards at the time of publication. (*Note: The standards for the states shaded in blue have changed since the publication date and have been updated herein)*:

State	Advisory Level	State	Advisory Level
Alabama	24.5	Missouri	10.9
Alaska	14	New Jersey	5
Arizona	11	New Mexico	13.8
California	1 (PHG) 6 (MCL)	New York	5
Florida	4	Nevada	18
Hawaii	15	North Carolina	2
Kansas	10.9	Texas	17
Maine	1	Vermont	1 (prevent) 2 (enforce)
Maryland	11	Virginia	15
Massachusetts	2 (MCL)	Wisconsin	0.1 (prevent) 1 (enforce)

In addition, EPA has a similar chart in its Technical Fact Sheet for Perchlorate which includes standards for the additional states of Colorado, Illinois, Indiana, Pennsylvania, Utah, and Wyoming. (EPA, *Technical Fact Sheet – Perchlorate* (Nov. 2017) at page 4.[5]) Notably, the standards for the states in these two charts range from 1 µg/L to 26 µg/L,[6] all of which are well below EPA's proposed MCL of 56 µg/L.

Metropolitan also recommends that EPA consider the monitoring and compliance guidance provided by California and Massachusetts in the development of their respective perchlorate drinking water regulations.[7] The guidance provides information on when water agencies need to monitor for perchlorate, what happens if perchlorate is detected, and when to monitor for

[4] Available at https://oehha.ca.gov/water/public-health-goal-fact-sheet/final-technical-support-document-public-health-goal-perchlorate.
[5] Available at https://www.epa.gov/sites/production/files/2017-10/documents/perchlorate_factsheet_9-15-17_508.pdf.
[6] EPA includes in its chart the non-residential standard of 71 µg/L for Kansas, but the residential standard is 11 µg/L.
[7] California's monitoring and compliance guidance for perchlorate is available at: https://www.waterboards.ca.gov/drinking_water/certlic/drinkingwater/Perchlorate.html.

perchlorate again if no perchlorate is detected in the initial monitoring. (See Memorandum from California Department of Public Health to All Community and Nontransient-Noncommunity Water Systems (Oct. 12, 2007)[8].) California also provides information on minimum requirements for initial monitoring.[9]

2. **Metropolitan has concerns with EPA's underlying assumptions and analysis of national occurrence data for perchlorate: (1) EPA does not have an up-to-date accounting of perchlorate contamination, either as a drinking water contaminant or from cleanup activities; and (2) EPA excluded perchlorate data from California and Massachusetts which led to EPA's proposed 18 µg/L, 56 µg/L, or 90 µg/L MCL levels. Metropolitan recommends that EPA reanalyze national occurrence data for perchlorate while including data from California and Massachusetts.**

Metropolitan has two concerns with EPA's occurrence analysis: (1) EPA's reliance on older data from the first Unregulated Contaminant Monitoring Rule (UCMR 1) ignores other, more recent perchlorate occurrence data from around the country; and (2) much of EPA's analysis excludes data from California and Massachusetts.

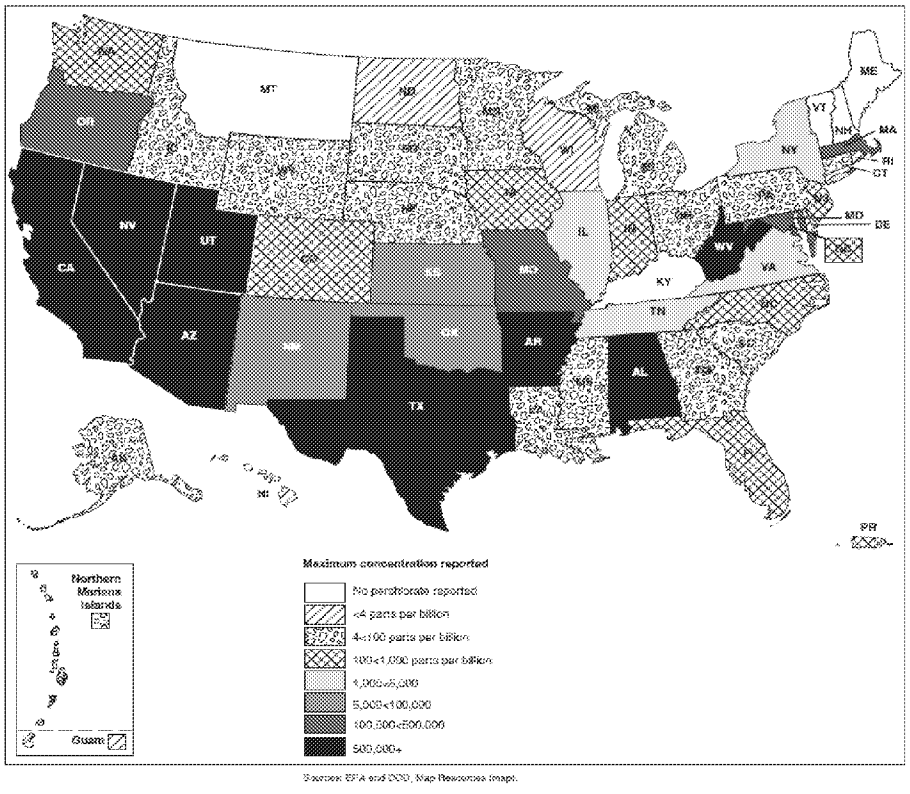
First, as EPA acknowledges, UCMR 1 data (which is based on monitoring conducted between 2001 and 2005) are "more than one decade old; actual occurrence could be lower (e.g., because of contaminant cleanup) or **higher** (e.g., because new systems use perchlorate-contaminated source water)." (84 Fed. Reg. at 30556 (emphasis added).) In fact, in 2005, the United States Government Accountability Office (GAO) recommended that EPA "establish a formal structure to centrally track and monitor perchlorate detections." (GAO, *Perchlorate: A System to Track Sampling and Cleanup Results Is Needed, GAO-05-462 (Washington, D.C.: May 20, 2005).*) EPA officials disagreed with that recommendation, saying that they "already had sufficient information on perchlorate concentrations in various environmental media that indicated the extent of contamination nationally and that if EPA were to implement a tracking system, the agency would require additional resources." (GAO, *Perchlorate: Occurrence is Widespread but at Varying Levels; Federal Agencies Have Taken Some Actions to Respond to and Lessen Releases, GAO-10-769 (Washington, D.C.: August 12, 2010)* ("GAO Report, '*Perchlorate Occurrence*'") at p. 9.) However, as GAO pointed out, "**[W]ithout a formal system to track and monitor perchlorate findings and cleanup activities, EPA and the states do not have the most current and complete accounting of perchlorate as an emerging contaminant of concern, including the extent of perchlorate found and the extent or effectiveness of cleanup projects**." (*Id.*, emphasis added) Yet the older UCMR 1 data is "the primary source of occurrence data the EPA relied on to estimate the number of water systems (and associated population) expected to be

[8] Available at https://www.waterboards.ca.gov/drinking_water/certlic/drinkingwater/documents/perchlorate/AdoptionMemotoWaterSystems-10-2007.pdf.
[9] Available at https://www.waterboards.ca.gov/drinking_water/certlic/drinkingwater/documents/perchlorate/Perchloratemonitoringchart-10-2007.pdf.

exposed at levels of perchlorate which could potentially exceed the proposed and alternative MCL levels." (84 Fed. Reg. at 30541.)

As an example of more recent occurrence data that EPA could have considered,[10] the Department of Defense (DOD) reported perchlorate detections at 284 of its installations, or almost 70 percent of the 407 installations sampled from fiscal years 1997 through 2009, with detections ranging from less than 1 µg/L up to 2.6 **million** µg/L. (*Id.* at p. 10.) In addition, as of June 2010, EPA reported perchlorate detections at 40 sites on the National Priorities List. (*Id.* at p. 12.) As EPA recognizes in its Technical Fact Sheet on Perchlorate, as of October 2009, perchlorate had been detected at varying levels in drinking water, groundwater, surface water, soil or sediment in 45 states, the District of Columbia, and three U.S. territories (see Figure 2 below).[11] (EPA, *Technical Fact Sheet – Perchlorate* (Nov. 2017) at p. 3.)

Figure 2: Maximum Perchlorate Concentrations Reported in Any Media as of October 2009



Second, Metropolitan does not concur with EPA excluding results from California and Massachusetts for perchlorate measurements that equal or exceed either 18 µg/L, 56 µg/L, or 90 µg/L simply "because water systems in these States must meet limits below 18 µg/L." (84 Fed.

[10] EPA cites this data in its Technical Fact Sheet on Perchlorate. (See EPA, *Technical Fact Sheet – Perchlorate* (Nov. 2017) at pp. 2-3.)

[11] Figure 2 is from GAO Report, *Perchlorate Occurrence*, page 13.

Reg. at 30542.) The fallacy of this assumption is shown by the fact that even though California has an MCL of 6 µg/L, 230 of 9,341 public water wells in California sampled between 2007 and 2017 had at least one detection of perchlorate above 6 µg/L. (State Water Board, *Groundwater Information Sheet: Perchlorate* (Nov. 2017).)[12] There were 173 groundwater sources in Los Angeles County (88), San Bernardino County (62), and Riverside County (23) alone that detected perchlorate above 6 µg/L. (*Id.*) In fact, California's OEHHA found that the results of a survey of "an essentially random sample of people from the U.S." suggested that "probably everyone in California, as well as everyone in the U.S., is exposed to perchlorate through some source." (OEHHA, *Final Technical Support Document for Perchlorate in Drinking Water* (Feb. 2015) at pp. 1, 152.)

Furthermore, perchlorate has been found in groundwater basins within Metropolitan's service area. The vast majority of locations where perchlorate has been detected in the groundwater are associated with the manufacturing or testing of solid rocket fuels for the DOD and the National Aeronautics and Space Administration (NASA), or with the manufacture, storage, handling, or disposal of perchlorate (such as at the Aerojet Rocketdyne site in Azusa, California and the Jet Propulsion Laboratory/NASA in Pasadena, California). Past agricultural practices using fertilizers containing naturally occurring perchlorate have also been implicated in some areas. According to the State Water Board's water quality database, monitoring results from 2011 to 2014 indicate that 17 of Metropolitan's 26 member agencies have detected perchlorate in their service areas at levels greater than 4 µg/L from groundwater sources. Thus, EPA's determination that there is an "infrequent occurrence of perchlorate at 18 µg/L, 56 µg/L, or 90 µg/L" (84 Fed. Reg. at 30541) is flawed because it is based on the exclusion of results from California and Massachusetts (84 Fed. Reg. at 30542). Metropolitan recommends that EPA reanalyze the occurrence data for perchlorate for the nation by including occurrence data from California and Massachusetts.

Also, the sources of perchlorate found in California and Massachusetts may be located outside of those states. As explained below, perchlorate in Orange County Water District's (OCWD) groundwater in California was traced to the Colorado River and found to originate from the two industrial sites near the Las Vegas Wash in Nevada. The Colorado River Basin includes the states of Nevada, Wyoming, Utah, Colorado, Arizona, and New Mexico. As shown above, none of these states have MCLs for perchlorate, and although some have Advisory Levels for perchlorate, most are higher than California's MCL of 6 µg/L. However, California's drinking water standard for perchlorate is not enforceable outside of the State. In addition, as shown on Figure 2 above, as of October 2009, several of the Colorado River Basin states had maximum perchlorate concentrations above 100 µg/L, some even higher than 500,000 µg/L. Protection of this source water is critical to the health and welfare of the residents in Southern California.

[12] Available at https://www.waterboards.ca.gov/gama/docs/coc_perchlorate.pdf.

Source water protection is critical to preventing perchlorate impacts not only to drinking water, but also to food. In 2004, the Food and Drug Administration (FDA) tested 500 samples of foods, including vegetables, milk, and bottled water for perchlorate. (Congressional Research Service, *Perchlorate Contamination of Drinking Water: Regulatory Issues and Legislative Actions* (Sept. 21, 2010) at pp. 1-2.) The FDA found perchlorate in approximately 90% of lettuce samples (average levels ranged from 11.9 µg/L to 7.7 µg/L), and in 101 of 104 bottled milk samples (with an average level of 5.7 µg/L). (*Id.* at p. 2.) The detection of perchlorate in food is relevant to EPA's rulemaking because EPA considers non-water exposures when determining whether to establish a standard for a contaminant and, if so, at what level. (*Id.*)

3. Metropolitan asks EPA to establish a drinking water standard for perchlorate that supports the ongoing remediation efforts and target cleanup goals at two chemical manufacturing facilities near Henderson, Nevada.

The Colorado River is a significant source of drinking water to approximately 19 million people in Southern California, as well as millions of people in Arizona, Nevada, and northern Mexico. Perchlorate was first detected in Colorado River water in 1997 and traced back to the Las Vegas Wash, which discharges into Lake Mead. The source of contamination was found to be emanating from two chemical manufacturing facilities near Henderson, Nevada: (1) a former Kerr-McGee facility which was owned by Tronox LLC and is now owned by the Nevada Environmental Response Trust (NERT); and (2) the former Pacific Engineering and Production Company of Nevada (PEPCON) site which was acquired by American Pacific Corporation (AMPAC) and is now operated by Endeavour, LLC. Under the oversight of the NDEP and EPA, there has been significant progress in reducing the loading of perchlorate into the Las Vegas Wash. At the time that perchlorate was first discovered, loading into the Wash was approximately 1,000 pounds per day, resulting in perchlorate levels exceeding 20 µg/L at times within Lake Mead. Interim remedial efforts have resulted in over a 90 percent reduction in perchlorate loading into the Las Vegas Wash, with levels decreasing from a high of 1,200 µg/L in 1998 to current levels between 50 and 70 µg/L on average. Further remediation is required to achieve greater reduction of perchlorate levels in the Wash. Due to ongoing cleanup activities, perchlorate levels in Lake Mead and the downstream Colorado River have typically remained below 2 µg/L over the past several years.

While the remedial efforts to date have been successful in reducing perchlorate loading into the Las Vegas Wash, a large perchlorate mass still remains at the Henderson sites. Groundwater at the NERT site contains high concentrations of perchlorate, up to 6,000 mg/L, and continues to migrate downstream towards the Wash and ultimately to the Colorado River. NERT is still conducting its remedial investigation of the site and downgradient areas and will then evaluate various long-term remedial alternatives. Currently, NERT is targeting groundwater cleanup to meet the interim federal drinking water health advisory level of 15 µg/L and Nevada's provisional action level of

18 µg/L (which is based on EPA's 1999 *Interim Assessment Guidance for Perchlorate*[13] (see NDEP's *Defining a Perchlorate Drinking Water Standard)*[14] within the Las Vegas Wash. EPA is working closely with NDEP to ensure that perchlorate releases to the Las Vegas Wash and Lake Mead are reduced effectively in a timely manner. Remedial construction of the long-term remedy for the NERT site is not expected to begin until late 2024/early 2025. Endeavour's long-term remedy, in operation since September 2012, has demonstrated a steady performance. Under the direction of NDEP, Endeavour has recently proposed modifications to their treatment system to remove perchlorate in surface drain waters not currently captured by their groundwater treatment system.

As an example of the Henderson sites' far-reaching impact, Metropolitan faces significant potential liability as a result of the perchlorate from the NERT site in Metropolitan's water supply. For example, in 2004, OCWD filed a lawsuit against several industrial defendants, alleging that they were responsible for contaminating OCWD's groundwater primarily with volatile organic compounds (VOCs). Subsequently, OCWD advised defendants that the remediation costs had increased considerably due to the presence of perchlorate in groundwater. In 2008, the defendants filed cross-claims against Metropolitan based on Metropolitan's sale of water containing perchlorate to OCWD for replenishment purposes. The source of the perchlorate in Metropolitan's Colorado River water was from the two chemical manufacturing sites near the Las Vegas Wash. Metropolitan incurred substantial costs defending itself in the case before trial. The trial was divided into phases, with the cross-claims against Metropolitan reserved for a later phase. At the end of the initial phase of the trial, the court ruled in favor of the industrial defendants. The appellate court subsequently reversed the judgment on two of OCWD's claims against one of the defendants, and affirmed the rest of the judgment. The case has been remanded to the trial court for further proceedings between OCWD and the remaining defendant. Thus, Metropolitan is still subject to potential cross-claims for the perchlorate cleanup costs.

In addition, because the target cleanup goal at the NERT site is based on EPA's 1999 *Interim Assessment Guidance for Perchlorate*, Metropolitan believes that EPA's proposed drinking water standard for perchlorate at 56 µg/L could adversely impact the ongoing cleanup efforts at the site. EPA's proposed MCL and MCLG of 56 µg/L are almost four times greater than the current target cleanup goal of 15 µg/L and could result in the cleanup goal being increased to a higher number. The alternative proposed MCL and MCLG of 90 µg/L are also much greater than the current target

---

[13] In 2003, EPA re-affirmed its 1999 *Interim Assessment Guidance for Perchlorate* with an added suggestion "to carefully consider the low end of the provisional 4-18 ppb range." (Memorandum from EPA Assistant Administrator Marianne Lamont Horinko to Assistant Administrators and Regional Administrators, "Status of EPA's Interim Assessment Guidance for Perchlorate" (Jan. 22, 2003) (emphasis added).)

[14] Available at https://ndep.nv.gov/uploads/env-sitecleanup-active-bmi-perchlorate/perchlorate-drinking-water-standard.pdf.

cleanup goal. In fact, if the cleanup goal at the NERT site was revised to 90 µg/L, perchlorate levels may increase significantly in the Las Vegas Wash and in the downstream Colorado River.

EPA's alternative proposed MCL and MCLG of 18 µg/L are very close to the current cleanup goal at the NERT site of 15 µg/L and, thus, would likely not adversely impact site remediation efforts. Nevertheless, as explained in comment #1 above, it is possible that California's MCL for perchlorate could decrease to 1 µg/L or a level close to 1 µg/L in the near future. If so, it is even more important that EPA's MCL and the target cleanup goal at the NERT site be low enough so that appropriate remedial measures are in place to reduce perchlorate loading into the Las Vegas Wash. This will help enable water agencies in California to comply with any lower California MCL and possibly prevent their exposure to additional litigation and potential liability based on impacted Colorado River water quality.

Treating perchlorate contamination at the source in the Henderson, Nevada area is the most cost-effective way to protect public health rather than shifting that burden to millions of downstream Colorado River water users. Thus, given the negative impact that EPA's proposed MCLs of 56 µg/L and 90 µg/L could have on the remediation at the NERT site and the subsequent negative effect on downstream Colorado River water users, EPA's conclusion that "no alternative MCL, including the alternative MCL values of 18 µg/L and 90 µg/L . . ., would 'maximize health risk reduction benefits at a cost that is justified by the benefits'" (84 Fed. Reg. at 30557) is incorrect. For these reasons, EPA's proposed drinking water standard for perchlorate should take into consideration the long-term remediation of perchlorate contamination at the Henderson sites to a level that is protective of public health for downstream Colorado River water users and that helps achieve California's current and possible future MCL for perchlorate.

4. Metropolitan urges EPA not to withdraw its February 11, 2011, determination to regulate perchlorate in drinking water.

Metropolitan urges EPA not to withdraw its February 11, 2011, determination to regulate perchlorate in drinking water. If EPA withdraws its intent to regulate perchlorate, and subsequently, perchlorate treatment were to be discontinued at the Henderson sites, perchlorate levels in the Colorado River could revert to 9 µg/L in as little as 12 months. This level of perchlorate would impact drinking water utilities in Arizona and Nevada which rely on Colorado River water, and would result in California drinking water utilities that rely on Colorado River water not being able to comply with California's existing MCL for perchlorate of 6 µg/L, potentially exposing them to additional litigation and liability. The NERT site cleanup is funded solely from private funds obtained, in part, from the participation of Metropolitan, CAP, and SNWA in litigation in order to protect their source water and achieve compliance with the state regulations they are subject to. EPA, as the nation's environmental steward, should continue to support the efforts of NDEP to reduce the level of contaminants entering the Colorado River, a primary source of drinking water for over 25 million people.

Furthermore, federal regulation of perchlorate under the Safe Drinking Water Act (SDWA) is important to provide a source of funds to clean up perchlorate. For example, the purpose of the Drinking Water State Revolving Fund (DWSRF) program is to assist public water systems with financing the costs of infrastructure necessary to achieve or maintain compliance with SDWA requirements and to protect public health. Section 1452 of the SDWA authorizes EPA's Administrator to award capitalization grants to States, who in turn provide low interest loans and other types of assistance to eligible drinking water systems. If EPA decides not to regulate perchlorate in drinking water, this source of funds will not be available to water agencies that have to bear the financial burden of cleaning up perchlorate in their drinking water supplies. Metropolitan recommends that EPA regulate perchlorate in drinking water at a level that would support the current target cleanup goal of 15 µg/L for the NERT site.

As a regional water provider with source water originating in multiple jurisdictions, Metropolitan supports the federal regulation of perchlorate at a level that: (1) prevents drinking water contamination through source water protection; (2) is protective of public health for Colorado River water users; and (3) helps to achieve California's current and potential future MCL for perchlorate. EPA's role in establishing and enforcing a national drinking water standard for perchlorate will be critical in the long-term remediation of perchlorate contamination in the Colorado River Basin and hundreds of DOD sites around the country.

Metropolitan appreciates this opportunity to provide input to EPA on the various options for regulating perchlorate in public drinking water systems and requests that EPA carefully consider these comments. Please contact Dr. Mic Stewart, Metropolitan's Water Quality Section Manager, at (213) 217-5696 or mstewart@mwdh2o.com if you have any questions or need additional information.

Very truly yours,

Re: comments on proposed perchlorate Maximum Contaminant Level, Docket No. EPA-HQ-OW-2018-0780

Dear Dr. Hernandez:

The Office of Environmental Health Hazard Assessment in the California Environmental Protection Agency is pleased to provide comments on the U.S. Environmental Protection Agency's proposed Maximum Contaminant Level (MCL) for perchlorate in drinking water (Federal Register of Wednesday, June 26, 2019 (84 FR 30524) (FRL-9994-68-OW).

The California Office of Environmental Health Hazard Assessment (OEHHA) believes that the Maximum Contaminant Level Goals (MCLGs) and Maximum Contaminant Levels (MCLs) recently proposed by the US Environmental Protection Agency (US EPA) for perchlorate (US EPA, 2019) are not adequately health-protective. In developing these levels, US EPA has taken approaches in a number of important areas that are not fully justified, not appropriate, and that need to be reconsidered. We have a large number of concerns with the proposed MCLGs and MCLs and the methods used to develop them. Our key areas of concern are described below.

Comments on the US EPA Proposed MCL/MCLG for Perchlorate

I. PBPK/PD MODEL: ASSUMPTIONS AND VALIDATION

A. The model is complex, includes a number of assumptions and is not reviewable without additional information

The US EPA proposal is based on a physiologically based pharmacokinetic/pharmacodynamic (PBPK/PD) model (coupled with a dose-response model) that is extremely complex (US EPA, 2017a). While we understand the reasons for attempting to link perchlorate exposure with hypothyroxinemia and neurodevelopmental outcomes, and appreciate the effort that has gone into developing the biologically-based dose-response (BBDR) model, the complexity of these models and the lack of documentation to support them result in a significant lack of transparency. More specifically, the US EPA proposal itself does not provide adequate justification or documentation for many of the assumptions used in the models or the approaches US EPA has used to attempt to validate these models. Because of this lack of information, it is extremely difficult to interpret the validity of the models, and it is not possible to fully evaluate them or to provide very specific comments on the modeling process in the timeframe US EPA has provided for public comment. Overall, based on this lack of transparency, we do not feel it is appropriate for US EPA to use these models as the primary basis of their proposed standards at this time.

B. Model validation

Importantly, the PBPK/PD model US EPA is proposing to use has not been validated for the most sensitive subpopulations: pregnant women, their fetuses, and infants. Calibration or validation with healthy non-pregnant adults is not appropriate since, as noted by US EPA, healthy non-pregnant adults are not one of the more susceptible groups. Comparisons to short-term dosing studies (e.g., Greer et al., 2002) are also problematic since adults have several months of stores of thyroid hormone, and these stores can temporarily mask any deficiency in thyroid hormone production that may be caused by perchlorate. Calibration or validation using animal data is not especially suitable since key aspects of the hypothalamic-pituitary-thyroid axis and key aspects of neurodevelopment differ markedly between species.

Although US EPA appears to have compared some aspects of the model to data from some human studies, the major outcomes of the model (e.g., the impacts of perchlorate on free thyroxine (fT4) levels) or critical precursor events (e.g., thyroidal iodide uptake) have not been shown to match the results of research studies in the most sensitive

groups. For example, in an independent analysis by Clewell et al. (2019), predictions from the US EPA PBPK/PD model were compared to the results of four studies in humans; only two of these studies involved pregnant women and none involved young infants. One of the studies in pregnant women (Téllez Téllez et al., 2005) used by Clewell et al. to compare to US EPA's modeling results was essentially an ecologic design, involving pregnant women with iodine levels that were much higher than commonly seen in the US, and took place in parts of Chile that had well- documented high exposures to other toxic agents (Cortés et al., 2016; Hopenhayn et al., 2003). Thus, this comparison is not particularly informative. In the other comparison, using by far the largest study in pregnant women (Steinmaus et al., 2016), the risks of declining thyroid hormone levels associated with perchlorate were under-predicted by the US EPA model by up to 100-fold. The key advantages of this particular study were: its large size; statistically significant results; consistency of effects for fT4, total thyroxine (T4), and thyroid stimulating hormone (TSH); inclusion of pregnant women from the US; and availability of information on a wide range of potential confounding variables such as iodine status, anti-thyroid antibodies, and socioeconomic indicators (Steinmaus et al., 2016). US EPA provides no explanation why its model so severely under-predicts this human research study. Overall, we feel it is inappropriate for US EPA to rely on a model that has not been adequately validated and that produces risk estimates that are far below those of the largest study to date on perchlorate and thyroid hormones in pregnant women.

II. INADEQUATE INCORPORATION OF UNCERTAINTY

One of the key areas of uncertainty noted by US EPA is the variation and uncertainty in the relationship between exposure and response among the members of the human population, that is, intraspecies variability. In developing its proposed MCLGs/MCLs, US EPA applied an intraspecies uncertainty factor of 3 to the point of departure (representing a 2% drop in IQ) to arrive at a reference dose. Typically, US EPA uses a default intraspecies uncertainty factor of 10. While regulatory agencies often decrease the toxicokinetic component of the intraspecies uncertainty factor when PBPK/PD modeling is used, the use of complex PBPK/PD models with a large number of assumptions does not necessarily reduce uncertainty.

In its 2005 review, an expert committee of the National Research Council recommended that US EPA use a factor of 10 to account for uncertainty in developing its perchlorate reference dose (NRC, 2005). This was consistent with US EPA guidelines that also call for a default uncertainty factor of 10 for intraspecies uncertainty (US EPA, 2002). In addition, US EPA's previous reference doses and its previous health advisories for perchlorate have used this same uncertainty factor (US EPA 2008a and 2008b).

Importantly, each of these previous documents and recommendations involved a reference dose that was based on human data (albeit in nonpregnant adults and using short-term exposure), not estimates from complex and uncertain models. A number of other experienced regulatory bodies have also used or recommended an uncertainty factor of 10 or higher in their perchlorate risk assessments (MassDep, 2006; OEHHA, 2015; New Jersey DEP, 2006).

In spite of these guidelines and recommendations, and without, in our view, adequate justification or supporting information, US EPA has decided to lower its intraspecies uncertainty factor from 10 to 3. For the reasons described below, we believe this decision is unjustified and not health-protective.

First, in its 2002 guidance document, "A Review of the Reference Dose and Reference Concentration Process," US EPA recommends reducing the intraspecies uncertainty factor from a default of 10 "only if data are sufficiently representative of the exposure/dose-response data for the most susceptible subpopulation(s)" (US EPA, 2002). Importantly, the information US EPA is using to develop its proposed MCLGs/MCLs is not from actual susceptible human populations. Rather, the information forming the basis of their assessment comes from estimates developed from models that have a large number of parameters, lack transparency, have considerable complexity, have not been adequately validated, and which therefore are associated with considerable uncertainty. Further, as mentioned above, the model severely underpredicts the effects seen in Steinmaus et al. (2016), the largest study of perchlorate in pregnant women to date. Based on all of these issues, there is no reason to believe that US EPA's model predictions are "sufficiently representative of the exposure/dose-response data for the most susceptible subpopulation(s)", and thus provide no valid justification for reducing the intraspecies uncertainty factor from the default level of 10.

Second, US EPA chose a point of departure "designed to provide an adequate margin of safety for the fetuses of mothers with an fT4 at the 10^{th} percentile of a population, an iodine intake of 75 µg/day, and a TSH feedback loop that is less than 60% as effective as individuals with a median TSH feedback loop efficacy." In deciding to model populations with an iodine intake of 75 µg/day, US EPA rationalizes that: "This value represents an intake between the 15th and 20th percentile of the women of child bearing age population distribution of estimated iodine intake from the National Health and Nutrition Examination Survey (NHANES). The EPA considered using a lower iodine intake level of 50 µg/day, which represents approximately the 5th percentile of the NHANES distribution. At 50 µg/day of iodine intake, however, the BBDR model predicts TSH levels that would be elevated to within the clinically hypothyroid range before

exposure to any perchlorate. In contrast, at 75 µg/day iodine, the BBDR modeled concentrations of serum fT4 and TSH are significantly reduced from the population median but are still within the euthyroid range." We see a major problem with this approach. That is, by choosing not to model women who are hypothyroid or women with low iodine intakes (i.e. below 75 µg/day), US EPA is essentially excluding two groups of women that are likely to be at very high risk from exposure to perchlorate. As such, US EPA's statement that an uncertainty factor of 3 is appropriate because the point of departure is based on the most sensitive members of the population of pregnant women is not justified.

Third, by attempting to include factors such as iodine intake, low baseline fT4 levels, or inter-individual differences in the sensitivity of the thyroid hormone feedback loops into their PBPK/PD model, US EPA has tried to incorporate some aspects of inter-human variability into their proposed MCLGs/MCLs. However, since the model has not been fully validated and since it is based on several questionable parameters, it is unknown whether any of these particular factors have truly been accounted for. As such, considerable uncertainty related to each of these remains.

Fourth, there are a number of other areas of uncertainty and potential areas of increased susceptibility that are not incorporated into US EPA's proposed MCLGs/MCLs. Some of these are specifically acknowledged by US EPA (pages 52-53), including uncertainty related to:

- Inter-individual differences in the competitive inhibition at the sodium iodide symporter (NIS)
- The depletion of iodide stores under different iodine intake levels and physiological states
- The lack of dose-response information linking fT4 to IQ from the US
- A lack of full information on the iodine intake status of the population used to estimate the dose-response relationship between maternal fT4 and childhood IQ
- The methods used to assess maternal fT4 measurement during pregnancy
- The true distribution of fT4 for a given iodine intake
- The possibility of sensitive life stages other than the first trimester fetus
- The lack of information linking incremental changes in infant thyroid hormone levels to adverse neurodevelopmental outcomes
- The potential role of the low levels of iodine storage in the fetus and infant
- The potential role of iron deficiency and its relationship to hypothyroxinemia in pregnant women
- The role of exposure to other chemicals that, like perchlorate, can also inhibit iodide uptake into the thyroid gland including nitrate (from drinking water and food) and thiocyanate (from food and tobacco smoke). These very common chemicals may have additive or synergistic effects with perchlorate in women or neonates who are co-exposed

- Uncertainty as to whether US EPA's incorporation of the variability in fT4 responses to TSH adequately reflect the true variability in the population.

Several other areas of uncertainty exist, and these are also not incorporated into US EPA's proposed MCLGs/MCLs. These include:

- Co-exposure to chemicals, including a number of pesticides or common industrial contaminants such as polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), bisphenol A, and per-/polyfluoroalkyl substances (PFAS), that may alter thyroid hormone levels or thyroid function by mechanisms other than thyroidal iodide uptake inhibition.
- Susceptibility due to other pre-existing thyroid diseases or the presence of anti-thyroid antibodies (thyroglobulin antibody and thyroid peroxidase antibody). US EPA has attempted to incorporate susceptibility related to low baseline values of fT4, but as mentioned above the models are still based only on euthyroid women. Importantly, not all pregnant women are euthyroid. (As noted above, US EPA did not model women who were hypothyroid, only those with hypothyroxinemia in the first trimester). Overall, there are many thyroid conditions that could affect an individual's susceptibility to perchlorate, and it is unlikely that US EPA has accounted for a number of them.
- Misclassification of fT4 levels in the Korevaar et al. (2016) study linking maternal fT4 to offspring IQ. Free thyroxine levels were only measured at a single point in time in this study. However, thyroid hormone levels can fluctuate over time, and pregnancy is a period of major changes in thyroid hormone levels (Lambert-Messerlian et al., 2008). As such, a single measurement of fT4 may not accurately reflect true long-term thyroid hormone status. Additional misclassification can occur due to the changes in binding protein levels that take place during pregnancy. These changes are known to adversely affect the test used to measure fT4 (Sapin and d' Herbomez, 2003). Because misclassification due to these factors is unlikely to be related to neurodevelopment, the resulting bias is most likely towards the null, that is, towards finding a weaker relationship between maternal fT4 and childhood IQ than what actually exists. Correcting for this bias would most likely increase the fT4-IQ association reported by Korevaar et al. and thus most likely decrease the reference dose and MCLGs/MCLs proposed by US EPA.

In conclusion, considerable uncertainty is present in the proposed MCLGs/MCLs but US EPA presents little justification for lowering its intraspecies uncertainty factor by >300%. Its decision to use such a low uncertainty factor is inconsistent with its own recommendations and past practices as well as the recommendations and past practices of other experienced agencies and experts. As we have described above, a large number of uncertainties exist in US EPA's proposed approach, and we do not agree that all, or even most, of them have been accounted for. Thus, we do not agree with applying an uncertainty factor of 3. Rather, at a minimum, the uncertainty factor should be 10.

III. THE USE OF A SINGLE STUDY ON NEURODEVELOPMENT

A. Other endpoints are not considered

In its most recent review, an expert committee of the National Research Council identified inhibition of iodide uptake by the thyroid and subsequent thyroid deficiency as the primary mode of action of perchlorate, and stated that, "...if it does not occur, there is no progression to adverse health effects" (NRC, 2005). By choosing a critical early effect like this as the basis for risk assessment and standard setting, all of the potential adverse effects that result from it, both known and unknown, should be prevented. Based on this principle, the NRC committee concluded that the "use of inhibition of iodide uptake by the thyroid as the basis of the perchlorate risk assessment to be the most health-protective and scientifically valid approach." The fact that there may be currently unknown or poorly described consequences of NIS inhibition and thyroid deficiency does not seem to have been considered by US EPA. The functions of thyroid hormone are complex and multi-faceted, and it is likely that there are a number of unknown or not yet well-described adverse effects of thyroid deficiency and perchlorate exposure.

In its draft proposal however, rather than using iodide uptake inhibition, US EPA now bases its MCLG/MCLs on a single downstream event, IQ loss. While we acknowledge that IQ loss is an important endpoint, it is unknown whether this is the most sensitive endpoint. In other words, it is unknown whether protecting against this particular outcome will help protect against all or even most of the other potential adverse outcomes that could be caused by perchlorate. Thyroid hormone is involved in many important physiological processes and plays a role in a number of important adverse events ranging from cardiovascular disease to alterations of digestive and muscle function to deficiencies in neuro- and physical development. Neurodevelopment is also complex and multifaceted, and we are not aware of any evidence suggesting that a single metric like IQ accounts for all aspects of this highly complicated process. By basing its MCLG/MCLs on a single highly specific downstream event like IQ, rather than on a very well-documented and relatively easily measured critical precursor event like iodine uptake inhibition, it seems likely that US EPA's current approach could have missed some of the more sensitive effects of thyroid deficiency and perchlorate.

B. The most sensitive neurodevelopment endpoint may not have been selected

With regards to neurodevelopment, US EPA identified five papers and seven analyses that they found useful for estimating the dose-response relationship between maternal fT4 and neurodevelopment. The outcomes assessed varied from study to study and included IQ, Mental Development Index (MDI), and Psychomotor Development Index (PDI), anxiety/depression scores, and reaction time. Of the five studies and seven analyses, US EPA selected its own re-analysis of a single study, the investigation of childhood IQ by Korevaar et al. (2016). For several reasons, we believe the use of this study by US EPA as its sole source of information on the fT4-neurodevelopment relationship is inappropriate and not adequately justified.

First, except for the Finken et al. (2013) study involving reaction time, the Korevaar et al. study had the least conservative dose-response slope of any of the seven analyses considered by US EPA. For example, the slope US EPA derived using the Korevaar et al. data was 3.5 times lower than that reported in the study of maternal fT4 and offspring PDI of Pop et al. (1999). If the goal is to develop an MCLG or MCL that is appropriately health protective, selection of a study with one of the least sensitive endpoints will not achieve this goal. It should also be noted that the urinary iodine levels in the women in the Korevaar et al. study appeared to be much higher (227 µg/g creatinine) than levels typically seen in US pregnant women. As such, the findings of this study may not be representative of much of the US.

Second, several of the studies of fT4 and a neurodevelopmental outcome were excluded for reasons that were difficult to follow. For example, US EPA decided not to use one study because the measured endpoint of "anxiety/depression is not an intuitively interpretable endpoint," without explanation of what is meant by "intuitively interpretable." In addition, a study of maternal hypothyroxinemia and cognitive and behavioral deficits in children by Vermiglio et al. (2004) was discussed extensively in a previous US EPA document on perchlorate (US EPA, 2017b) but is not even cited in the draft proposal. This omission is important because the magnitude of the association between fT4 and IQ reported by Vermiglio et al. was almost four times greater than that reported by Korevaar et al. (US EPA, 2017b).

US EPA appears not to have used the Pop et al. (1999) and Pop et al. (2003) studies because of their small sample sizes and because neither was adjusted for confounders. However, sample size was not a major problem with either study since both were large enough to identify findings that were statistically significant. As noted previously by US EPA, "a small study that does detect an association is notable given the lack of power that is associated with a small sample size" (US EPA, 2017b). Further, it is not appropriate to exclude a study based on confounding without doing an adequate evaluation of this bias. While there are a number of methods to do this (see Axelson,

1978 as an example), none of these are presented in the draft proposal. For example, we note that while the results of Pop et al. (1999) using fT4 and PDI as continuous variables were not adjusted, categorical analyses presented in this study showed that a strong association between fT4 and PDI remained after adjustment for education, smoking, anti-thyroid antibodies, maternal depression, and other factors. In Pop et al. (2003), women with depression, obstetrical complications, or clinical or subclinical thyroid conditions, and children with low birth weight or hospitalizations were excluded. These exclusions should have removed any important confounding caused by each of these factors. For other variables, such as maternal and paternal education levels, smoking, alcohol intake, income, breastfeeding, birth weight, and gestational age, major differences were not seen between women with low and high fT4 levels in this study, suggesting that confounding by these variables is unlikely. These are a few examples of the types of analyses that can be done to evaluate confounding but they do not appear to be a part of the development of the proposed MCLGs/MCLs.

The two Pop et al. papers discussed above assessed the impacts of maternal fT4 and neurodevelopment using the Bayley Scales of Infant Development. US EPA has previously described these scales as, "the gold standard for neurodevelopmental assessment of children" and "a reliable indicator of the current development and cognitive functioning of the infant" (US EPA, 2017c). The MDI scale of the Bayley test evaluates aspects of functioning such as eye hand coordination, manipulation, understanding of object relations, imitation, and early language development. The PDI scale of the Bayley test assesses gross motor development. While the ability of the Bayley scales in young children to predict future outcomes may not be as strong as IQ in later life, this does not mean that the Bayley scales are not important. Rather, they are a commonly used metric for assessing early life development and several studies have shown that they have at least some predictive value for future outcomes (Siegel, 1982; Van Baar and de Graaff, 1994; Van Wassenaer et al. 1997; Luttikhuizen dos Santos, 2013). By excluding the two Pop et al. studies for reasons that are not clear, US EPA may have unjustifiably excluded two valid sources of information on outcomes that could be more sensitive than IQ.

Categorical data can also be used for risk assessment, and US EPA identified a number of studies using categorical data that reported fairly clear associations between thyroid deficiency and neurodevelopment (US EPA, 2017b). In fact, in an earlier document, US EPA noted that out of the 13 studies (and two meta-analyses) it identified that used categorical data, 11 found evidence for an association (US EPA, 2017b). However, none of these studies were used to develop the proposed MCLG/MCLs. Studies or analyses involving thyroid hormones other than fT4, specifically thyroid stimulating hormone (TSH), studies of other thyroid disorders (e.g. hypothyroidism), and studies not

involving the first trimester of pregnancy were also not used. These exclusions may have also led to some sensitive outcomes being missed. For example, based on its earlier PBPK/PD modeling, US EPA estimated that the drinking water level of perchlorate estimated to cause a 10% increase in TSH was 3 µg/L. This is 19 times lower than the currently proposed MCLG/MCL of 56 µg/L (US EPA, 2017b) which is based solely on fT4. And, in its 2017 methodology paper on perchlorate, US EPA calculated a point of departure (POD) of 0.4 µg/kg-day for a one percent increase in the number of women with hypothyroxinemia. This is 17 times lower than the POD of 6.7 µg/kg-day US EPA used to calculate the proposed MCLG/MCL of 56 µg/L (US EPA, 2017b). Overall, by essentially ignoring all of these other studies and other outcomes, it is very likely that US EPA's proposed MCLGs/MCLs are not based on the most sensitive adverse effect.

In summary, while US EPA identified several different studies of fT4 and neurodevelopment, it has selected an endpoint that gives one of the least sensitive dose-response relationships and therefore inappropriately high MCLGs/MCLs. The main reasons why US EPA appears to have made this selection is that IQ is "intuitively interpretable," and that the Korevaar et al. study had a large sample size. However, neither of these factors means that the outcomes assessed in the other studies are not relevant, valid, or important. In order to help assure that the most sensitive known outcome is considered, we believe that US EPA should reconsider the information on the other studies of thyroid hormone and neurodevelopment it has identified. As shown in Table III-2 of the draft document (US EPA, 2019), use of the data by Pop et al. (1999 and 2003) would result in a reference dose that is approximately 3-times lower than that currently proposed by US EPA. This type of major difference in sensitivity should not be ignored if the goal is to develop an MCLG/MCL that is truly health-protective.

C. Re-analysis of original study findings by Korevaar et al. is not justified

Despite describing the original Korevaar et al. (2016) study as "the most rigorous analysis available in the literature to date," US EPA reanalyzed the Korevaar et al. data and used the results of this re-analysis in their models. This re-analysis was done in response to a peer review comment questioning the fit of the log-linear model originally used by Korevaar et al. and questioning whether the addition of certain variables in the model "may have driven [biased] measures of association towards the null." We agree with this reviewer's concerns in principle. However, the re-analysis done by US EPA did not result in an association that was further away from the null as the reviewer (and we) expected. Rather, the opposite occurred: the change in fT4 needed to cause a 1% decrease in IQ was 62% **higher** in US EPA's re-analysis than that originally reported by Korevaar et al. Overall, while we agree that model overfitting can sometimes be a

problem, in order to be fully transparent US EPA needs to show that the variables they removed from the original Korevaar et al. model really did cause overfitting and were not actual confounders. US EPA should also provide more information on whether or not their new model provides a better fit than the original model, and provide a rational explanation of why their re-analysis produced results that were in an unusual and unexpected direction. We do not feel it is appropriate for US EPA to use the results of their re-analysis of the Korevaar et al. data until these issues are adequately addressed.

IV. OTHER SUSCEPTIBLE GROUPS: INFANTS

Based on the recommendation of its Scientific Advisory Board, US EPA decided to focus on fetuses of hypothryoxinemic first-trimester pregnant women as the most sensitive subgroup. Importantly though, there are other sensitive subgroups and none of these have been included in US EPA's MCLG/MCL development.

The decision to focus solely on this group appears to be based on the assumption that the relationship between thyroid deficiency and adverse neurodevelopment is greatest during the first trimester fetal period. While we acknowledge that there is some evidence to suggest this may be the case, this evidence is far from conclusive, and a variety of other research suggests that thyroid function is critically important during other life stages. For example, in Pop et al. (2003), while maternal fT4 levels in the first trimester were strongly linked to neurodevelopmental outcomes in the offspring, this effect only occurred when maternal fT4 levels continued to remain low into the 2nd or 3rd trimesters. This highlights the importance of thyroid hormone throughout the entire pregnancy, not just during the first trimester.

A wealth of research also shows that adequate thyroid function in the neonatal and later infancy periods is important for neurodevelopment (Zoeller and Rovet, 2004). And, as reviewed by OEHHA (2015), several research studies have linked perchlorate to changes in thyroid hormone levels in young children (Steinmaus et al., 2010; Brechner et al., 2000; Kelsh et al.,2003; Buffler et al., 2006; Li et al., 2000; Crump et al., 2000). Even US EPA's own models have identified young infants as a major susceptible subpopulation. For example, in US EPA's 2009 PBPK/PD model, inhibition of iodide uptake into the thyroid gland at a given drinking water level of perchlorate was predicted to be about four times higher in bottle fed infants than in first trimester pregnant women (US EPA, 2009). Overall, based on all of this evidence, it seems highly unlikely that the impacts of thyroid deficiency on neurodevelopment completely disappear after the first trimester of pregnancy, and therefore it is unreasonable not to consider neonates or young infants as an important susceptible subpopulation.

Consideration of neonates or young infants is especially important because perchlorate intake on a per body weight basis at a given concentration of perchlorate in drinking water is markedly higher (almost six times higher) in bottle-fed infants than in first-trimester pregnant women (OEHHA, 2015). This fact does not seem to have been considered in US EPA's most recent proposal. Young infants may also be particularly susceptible to perchlorate because they have much lower levels of stored thyroid hormone than adults. These low reserves likely make infants much more susceptible than adults to any short-term reductions in thyroid hormone production that could be caused by perchlorate.

It appears that US EPA decided to exclude infants based on an earlier BBDR model and the assumption that iodine in infant formula would offset the effects of perchlorate. However, to our knowledge neither the results of this earlier model nor the assumption regarding iodine in formula have not been validated or confirmed. OEHHA's latest perchlorate Public Health Goal (OEHHA, 2015) used bottle-fed infants as the most susceptible subpopulation, and included a specific drinking water intake rate for bottle-fed infants. By not considering the much higher drinking water intakes rates in neonates and infants, and by not fully considering the risks in these young children, it is highly likely that US EPA's proposed MCLG/MCLs are not adequately protective for these important susceptible subpopulations.

V. A BENCHMARK RESPONSE OF 2% IS NOT HEALTH PROTECTIVE

The primary MCLG and MCL of 56 µg/L proposed by US EPA are based on a two-point (or 2%) loss in IQ, that is, a benchmark response (BMR) of 2%. An approach using a BMR of 1% is provided as an alternative, and this results in an MCL that is three times lower (the MCL is not directly proportional to the BMR because the relative source contribution of perchlorate from food is increased when lower BMRs are used). Importantly, US EPA provides no justification for why it selected a BMR of 2%. The US EPA's benchmark guidance notes that when assessing animal toxicological data, as a starting point the analyst might consider a benchmark response rate for continuous data as one standard deviation. In the case of IQ, that would be 15 IQ points, obviously not a good benchmark response rate for such an important outcome. In the draft proposal, US EPA states that it looked to its 2012 Benchmark Dose Guidance document for insight and specifically noted that, "[a] BMR of 1% has typically been used for quantal human data from epidemiology studies." (US EPA, 2012). While the guidance document does not recommend a specific BMR for continuous data, we see no reason why this recommendation should differ between quantal and continuous human data, particularly for an endpoint such as IQ.

The guidance document goes on to state that, "The ideal is to have a biological basis for the BMR for continuous data, e.g., a consensus scientific definition of what minimal level of change in a continuous endpoint is **biologically significant."** While a 1% decrease in IQ in an individual may or may not be noticeable, a 1% decrease in the average IQ in a large population certainly is *biologically significant*. For example, Bellinger (2004) has shown that while relatively small changes in IQ associated with lead exposure may have limited impacts at the individual level, they can cause major increases in the numbers of people at the low end of the IQ spectrum and major decreases in the numbers of people at the higher end of the IQ spectrum. Weiss has shown that this effect is even greater in disadvantaged populations (Weiss, 2000). Like lead, perchlorate exposure is widespread. That is, essentially everyone in the US is exposed (Blount et al., 2007), and in its draft document US EPA estimates that 4-16 million people may have perchlorate concentrations ≥4 µg/L in their drinking water. Given this widespread exposure, small changes in IQ due to perchlorate, including a 1% change, can have major population impacts and therefore should be considered biologically significant. As such, if IQ or any other major neurologic outcome is used as the basis of the MCLG/MCL, at a minimum, a 1% change should be selected as the BMR.

VI. SUMMARY

US EPA has made a number of key decisions that are not well supported and which have resulted in proposed reference levels and MCLGs/MCLs that are higher than the health- protective levels it has previously proposed and higher than those proposed by other agencies and experts. This includes its decision to use a model that is exceedingly complex and opaque, has not been appropriately validated, and which is associated with considerable uncertainty. It also includes its decisions to lower its uncertainty factor to a level markedly below its well-established default value, its decision to use a benchmark response that is higher than what most would consider biologically significant, and its decisions to not use the most sensitive endpoints or populations. Given these concerns, we would like to make the following recommendations:

1. US EPA should not use its current PBPK/PD model unless and until all parameters are well justified, it can be made more transparent (see Clewell et al., 2019), and it is appropriately calibrated and validated.
2. These parameters and this validation should be based on data from the most susceptible groups including pregnant women, fetuses, and young infants. We acknowledge that the appropriate data from fetuses for validation and calibration may never be available. This is a major underlying flaw in the PBPK/PD model that might never be overcome.

3. US EPA should use an intraspecies uncertainty factor of at least 10 in order to more appropriately account for sensitive populations besides the fetuses of pregnant women in the first trimester. These include bottle-fed infants, fetuses of pregnant women who are not euthyroid, women with very low iodine intakes, and other individuals with thyroid disease.
4. US EPA's benchmark response should be based on the most sensitive outcome or on a sensitive critical precursor event such as inhibition of uptake of iodide by the thyroid. The latter is the best way to help assure that all important adverse effects, both known and unknown, can be prevented.
5. If IQ or a similarly important outcome is selected as the critical event, a 1% decrease is likely to be biologically significant and should therefore be used as the benchmark response, rather than 2% IQ loss as in the current US EPA proposal.
6. US EPA should not use re-analyzed data (e.g., the Korevaar et al. analysis) unless the re-analysis is fully justified, the methods and results are transparent, and any discrepancies or unusual results are explained.
7. Neonates and infants should be considered a susceptible group and their very high water intake on a per body weight basis should be incorporated into any perchlorate risk assessment.

Sincerely,

General Comment

In the June 26, 2019 proposed rule for perchlorate, EPA requested comments on the costs and availability of Treatment Technologies as well as potential implementation challenges associated with the proposed perchlorate regulation that the EPA should consider, specifically for small systems. Innovative Water Care, LLC would like to offer the following comments regarding sources of perchlorate contamination and technologies that may be used to avoid perchlorate contamination.

In the EPA-HQ-OW-2018-0780-0127 Perchlorate occurrence and monitoring report, there isnt any breakdown of which systems used chlorine gas and which used sodium hypochlorite solutions, but there is a geographical distribution in Exhibits 16 and 17 that shows a greater occurrence of perchlorate in the southern states where warmer temperatures may be expected to accelerate sodium hypochlorite decomposition and formation of perchlorate. Furthermore, Exhibit A-3 indicates that the median finished water perchlorate concentration (16 ppb) is greater than the median surface (0.248 ppb) and ground (1.5 ppb) water concentrations. These data indicate that the chlorination process may be a contributing factor in perchlorate contamination.

In 2009, the American Water Works Association (AWWA) published the report Hypochlorite- An assessment of factors that influence the formation of perchlorate and other contaminants (AWWA 2009). The document provides data on the effect of storage conditions and other variables on perchlorate formation in sodium hypochlorite solutions and provides guidance on ways to avoid perchlorate formation. In addition to specific storage recommendations, the document provides data on the much lower perchlorate values of calcium hypochlorite.

As stated in the proposed rule, the Safe Drinking Water Act requires that the Agency list the technology, treatment techniques, and other means which the Administrator finds to be feasible for purposes of meeting [the MCL]. The Best Available Technologies (BAT) discussed in Section X of the proposed rule and in EPA-HQ-OW-2018-0780-0111 (Best Available Technologies and Small System Compliance Technologies for Perchlorate in Drinking Water) cover only remedial techniques for removing perchlorate from water. Since chlorination may be a preventable source of perchlorate contamination in drinking water, we believe that the BAT list should include preventative techniques as well as remedial techniques that are feasible for purposes of meeting the proposed MCL values. The guidance provided in AWWA 2009 should be incorporated as Best Available Technologies for prevention of perchlorate contamination. Following is a list of techniques that may be used to minimize perchlorate additions with chlorination:
Dilute stored sodium hypochlorite solutions upon delivery
Store sodium hypochlorite solutions at lower temperatures
Control the pH of stored sodium hypochlorite solutions at pH 11-13, even after dilution
Control the removal of transition metal ions by purchasing filtered hypochlorite solutions and by using low-metal ion concentration feed water for the on-site-generation systems
Use fresh hypochlorite solutions when possible
Make hypochlorite solutions on-site immediately before use by using feed equipment that dissolves solid calcium hypochlorite
Use alternate sources of chlorine where perchlorate contamination is decreased (chlorine gas and solid calcium hypochlorite)
All of these techniques are effective in minimizing perchlorate contamination of drinking water and all of them are appropriate for use by small systems. They meet all of the BAT criteria outlined in Exhibit 1 of EPA-HQ-OW-2018-0780-0111:
High removal efficiency (although the word reduction would be more appropriate here)
History of full-scale operation
General geographic applicability
Compatibility with other treatment processes
Ability to bring all of the water system into compliance
Reasonable cost basis for large and medium systems
These techniques also provide a reasonable cost basis for small systems.

An additional benefit is that these preventative measures do not produce any waste streams such as those that would be created with the currently listed

BAT remediation techniques of ion exchange, biological treatment and reverse osmosis.

EPN COMMENTS ON PROPOSED PERCHLORATE DRINKING WATER STANDARD

August 26, 2019

The Environmental Protection Network (EPN) is an organization comprised of over 450 EPA alumni volunteering their time to protect the integrity of the U.S. Environmental Protection Agency (EPA), human health and the environment. We harness the expertise of former EPA career staff and confirmation-level appointees to provide an informed and rigorous defense against current Administration efforts to undermine public health and environmental protections.

In the proposed new perchlorate drinking water standard, EPA acknowledges that the lack of robust epidemiology studies makes it very difficult to estimate the likelihood and magnitude of perchlorate's effects on neurodevelopment in fetuses and infants exposed to perchlorate through cord blood, breast milk, and formula. Despite this fact, EPA's proposed perchlorate standard is based on a reference dose (RfD) that includes the lowest possible uncertainty factor of three because the agency maintains all other uncertainty has been eliminated by the use of their Biologically Based Dose Response (BBDR) model. In our comments below, EPN describes the reasons why this uncertainty factor of three does not provide an adequate margin of safety for the perchlorate RfD and must be increased. EPN also comments that the novel approach EPA used to derive a Relative Source Contribution (RSC) for perchlorate must be peer reviewed by external experts before it can be used. Finally, EPN comments on implementation issues in the perchlorate proposal. Based on these concerns, EPN concludes that the proposed perchlorate drinking water standard is not scientifically defensible.

Risk Assessment

EPA derived the proposed Maximum Contaminant Levels (MCLs) using the BBDR model to estimate perchlorate impacts on the thyroid hormones of a pregnant woman at each gestational week from conception to week 16. The model predicts serum thyroid hormone levels of T4 given specific levels of iodine intake, thyroid stimulating hormone (TSH) feedback loop strength, and perchlorate doses. EPA then linked these model predictions of T4 levels to an epidemiology study's measurements of one day's T4 level in a pregnant woman and the intelligence quotient (IQ) of her child. EPA calculated proposed MCLs for perchlorate, which were predicted to produce a 1, 2 or 3% decrease in IQ for a child born to a woman with low iodine intake levels, low T4 levels, and weak TSH feedback strength.

EPN has a number of concerns regarding this approach. First, there were very few data available to calibrate the pharmacokinetic aspects of the model, particularly during the first trimester of pregnancy. Perchlorate and iodide absorption, metabolism and excretion are therefore uncertain. Second, pharmacodynamic data are lacking to calibrate the joint effect of varying perchlorate and iodide serum concentrations on thyroid uptake of iodide and subsequent production of T4 hormone levels from gestation to week 16. Third, the failure to conduct a systematic review of the epidemiology literature undermines the basis for linking the BBDR model results to neurodevelopmental outcomes. It is possible that the 66 studies eliminated from consideration could have provided key information for the overall weight of evidence regarding both serum thyroid function and the relative sensitivity of IQ compared to other neurodevelopmental measures. Even the five studies that EPA considered indicate that IQ is a less sensitive measure than the Mental Development Index and Psychomotor Development Index, which were evaluated in some of those studies.

Finally, EPN notes that there are multiple concerns with the epidemiology study used as the basis of the RfD. According to the American Thyroid Association, the reference range of TSH and T4 in pregnant women varies within the U.S. population and across ethnic groups. Thyroid hormone levels also vary throughout pregnancy, adding to the uncertainty in identifying the level of alteration that may lead to hypothyroidism and fetal effects. The selected epidemiology study involves a non-U.S. population, includes only a one-time measurement of T4 hormone in each pregnant woman, and does not measure iodine intake or perchlorate exposure for any of the women. This lack of critical data impairs the ability of the BBDR model to predict serum T4 hormone levels and the ability to link those hormone levels to an appropriately sensitive neurodevelopmental outcome. It is particularly concerning that EPA has not resolved the critical issues of uncertainty identified previously by the Science Advisory Board, which include the lack of epidemiology data showing a direct association between iodine inhibition and IQ decrement, predictions for lactating mothers with less than 75ug/day iodine intake, and the lack of a standard definition of hypothroxinemia. It appears that EPA is trying to set the precedent that use of a complex model with many variables, which cannot be calibrated, justifies the elimination of uncertainty factors for reference doses. That is not a scientifically defensible policy. EPN concludes that EPA cannot possibly justify the low uncertainty factor of three and should derive new RfDs before proposing a perchlorate drinking water standard.

EPN is also concerned that EPA developed a new methodology to estimate the perchlorate dose that women of childbearing age in the U.S. are getting from food but did not subject this influential analysis to expert external peer review before using it to calculate the proposed MCLs. The new method combines food consumption data for women of childbearing age, from National Health and Nutrition Examination Surveys, with Food and Drug Administration (FDA) data on the perchlorate concentrations in various types of food to calculate each study participant's daily dose of perchlorate. RSCs ranging from 56% to 88% for the three different RfDs were calculated using the 90th percentile bodyweight-adjusted perchlorate consumption based on the second-highest perchlorate concentrations measured by FDA for each type of food. EPA suggests this second-highest concentration is equivalent to a 95th percentile value but did not assign a distribution to the 20 samples available for each type of food. An expert external peer review is needed to evaluate this complex analysis, which is of great interest to women throughout the country who are unknowingly exposed to perchlorate in their food.

Implementation

In addition to our risk assessment concerns, we have the following comments regarding the implementation of the proposed perchlorate drinking water standard.

First, EPN has questions concerning EPA's assumptions about the extent and cost of the initial perchlorate monitoring required by the states and water systems. See Section VIII Monitoring and Compliance Requirements. EPA's estimate significantly overstates the number of water systems that will need to be monitored. It is highly likely that most consecutive systems will not need to to be monitored. States will use their discretion to waive the monitoring requirement where perchlorate is likely not to be found in the water system's source water. EPA must work with states to develop strong implementation guidance to minimize the initial monitoring round, as was done for most of the current regulations implemented in the middle 1990s for inorganic compounds, volatile organic compounds, and synthetic organic compounds. EPN recommends that EPA seek external comments on the high monitoring costs.

Second, EPN has major concerns about the adequacy of EPA's cost-benefit analysis of the proposed regulation. See Section XII Health Risk Reduction Analysis. EPA concluded that for all proposed MCLs, the total annual costs are substantially higher than the proposed benefits.

- The cost-benefit analysis supports the proposed MCL levels of 18, 56, and 90, where the benefits by definition are low since the expected violations to be resolved are very low. A cost-benefit analysis where the costs are much higher than the benefits weakens the validity of the proposal. EPN believes a more stringent standard is justified and that a more stringent value could result in benefits exceeding costs. EPN recommends that EPA withdrawal the current proposal and re-propose a new standard more stringent than the current proposal.
- The cost-benefit analysis itself is very weak. EPA acknowledged that they made many assumptions around the cost-benefit estimates that reduced the benefits estimate and potentially overestimated costs. *On benefits:* They purposely did not consider the obvious benefits of perchlorate treatment in addressing co-occurring violations, such as nitrate. Also, they made no assessment of treatment costs avoided by a water system's decision to switch to a new water source, which is what is happening in both Massachusetts and California to comply with their state perchlorate regulation. *On costs:* They made a very high estimate of the cost of initial monitoring, even though states have wide discretion to waive monitoring requirements for many water systems..

Third, EPN has serious concerns that EPA is including in their perchlorate proposal an option to withdraw from the 2011 regulatory determination and potentially not regulate perchlorate. See Section XV Request for Comment on Potential Regulatory Determination Withdrawal. The proposal states that recent findings suggest that perchlorate does not occur in water systems with a frequency and level of public health concern, and that the perchlorate regulation is no longer a meaningful opportunity for health risk reduction. They also point to EPA's previous determination in 2008 not to regulate perchlorate as precedent, as well as reference other EPA decisions to question regulation (e.g., aldrin) where the occurrence was very low.

EPN has identified serious flaws in the proposal and has serious questions about the scientific defensibility of the EPA perchlorate regulation, the validity of the monitoring, and cost-benefit analysis. EPN strongly recommends that EPA withdrawal the proposal and re-propose a more stringent perchlorate standard with a new cost-benefit analysis. The new proposal should delete the option to withdrawal from the 2011 regulatory determination.

Re: Proposed National Primary Drinking Water Regulation: Perchlorate
Docket No. EPA–HQ–OW–2018–0780

Dear Docket:

The Association of State Drinking Water Administrators (ASDWA) is the independent, nonpartisan, national organization representing the collective interests of the drinking water program administrators in the 50 states, five territories, the District of Columbia, and the Navajo Nation who implement the Safe Drinking Water Act (SDWA) every day to ensure the protection of public health and the economy. ASDWA supports and represents the collective interests of the states, territories, and the Navajo Nation in their administration of national drinking water program requirements within their states or territories. The following ASDWA comments are intended to broadly address the proposed rule, but they do not necessarily reflect the concerns of individual states.

ASDWA appreciates the opportunity to provide comments to EPA on the proposed perchlorate rule, as it is an important rulemaking. This proposal has been over 21 years in the making, with perchlorate being listed on the First Contaminant Candidate List (CCL1) in 1998 and included in the First Unregulated Contaminant Monitoring Rule (UCMR1) in 1999. ASDWA commends EPA for continuing to make regulatory progress throughout those 21 years, and for its focus on developing a better understanding of the challenging health effects data to use in its development of a perchlorate proposal.

ASDWA recognizes that EPA has taken a different regulatory approach for this proposal by proposing a MCLG and MCL of 56 µg/L, as well as MCL options of 18 µg/L and 90 µg/L. EPA used a similar approach for its proposal for the arsenic regulation in 2000, as EPA took comments on four proposed MCLs in that proposal. For perchlorate, EPA has also proposed an option for a negative regulatory determination based on new information indicating perchlorate does not occur with a frequency at levels of public health concern and there may not be a meaningful opportunity for risk reduction through a national drinking water regulation, as required by the Safe Drinking Water Act (SDWA).

1401 WILSON BLVD · SUITE 1225 · ARLINGTON, VA 22209
PHONE (703) 812-9505 · FAX (703) 812-9506 · info@asdwa.org · www.asdwa.org

The regulatory development process for perchlorate has been reworked several times since the late 1990s, as EPA proposed a negative regulatory determination in 2008 and then reversed that proposal with a positive regulatory determination in 2011. In the June 26th *Federal Register* (84 FR 30524), EPA published an option for a negative regulatory determination that would reverse the 2011 determination. Since the listing of perchlorate on CCL1 in 1998, two of ASDWA's members (California and Massachusetts) have developed their own state-level perchlorate standard for drinking water. Nevada is also using the interim health advisory as a groundwater cleanup action level for ongoing industrial cleanup actions action in Henderson, Nevada.

In the proposal, EPA did not take into the account the occurrence data (and the resultant treatment costs) for the states (California and Massachusetts) that have developed their own state-level perchlorate standard. One potential concern for future rulemakings based on this approach is, if the Agency continues to exclude states with state-level standards, future rules could be based on a smaller and smaller number of states with the inability to require monitoring or to establish state-level standards.

The ASDWA Board has decided to not take a position on whether to regulate perchlorate or not. The final decision on whether to regulate perchlorate or not is in the "sole judgment of the Administrator" and it is hard to argue one way or the other with that judgment call.

However, if EPA decides to move forward with a final regulation for perchlorate, ASDWA recommends that EPA consider the following items for the final regulation and implementation:

- **Monitoring waivers:** If EPA decides to move forward with a perchlorate regulation, monitoring waivers need to be a significant component of the regulation, as approximately 2/3 of the estimated burden is for monitoring costs. Another significant component of the estimated burden is administrative costs for states, and it should be noted that waiver processes are resource-intensive, and an additional estimate would need to be developed for the increased state administrative burden for waivers. Some states review monitoring waivers by each sampling point, not by each eligible system as calculated in the proposed rule. For those states that review waivers for each sampling point, 8 hours of state review time per eligible system is a gross underestimate. ASDWA recommends that EPA increase its estimate for the states' burden for monitoring waivers. EPA also needs to recognize that any regulatory strategy to reduce the monitoring burden by the water systems through waivers creates additional administrative burden for the states with the review of all the waivers. Additionally, as currently written, 141.23(c)(3)-(6) only requires states to consider previous monitoring history, variation in the results, and system changes in determining waiver eligibility. EPA's occurrence data states that perchlorate is highly mobile and persistent, and exposure can be from man-made sources. Using these sources of exposure in monitoring waivers determinations are not adequately covered in 141.23(c)(3)-(6). EPA would need to update this section of the rules and develop monitoring waiver guidance for states to include potential sources of perchlorate contamination, provide GIS source mapping for potential contaminant locations, when to void a waiver, and how to

address new potential sources of contamination (e.g., new munitions site). Each primacy agency should be able to create their own waiver language that would be approved by the EPA Region. For example, the past cyanide waiver language (based on no industrial uses of cyanide) in 141.23(c)(2) could potentially be modified for perchlorate.

- **Initial monitoring:** If EPA decides to move forward with a perchlorate regulation, then ASDWA recommends four quarters of initial monitoring, to be consistent with the standardized monitoring framework for other inorganic contaminants.
- **Monitoring costs:** As mentioned above, approximately 2/3 of the estimated burden is for monitoring costs. It should be noted that some states conduct the monitoring for water systems, and these costs should be included in the states' burden in the final regulation. More information is needed to determine which states collect and analyze samples for what size systems, but approximately 8-10 states collect and analyze some or all of compliance monitoring samples. EPA should work with ASDWA during the development of the final economic analysis to determine the appropriate split of monitoring costs between the states and the water systems.
- **MCL exceedances:** If EPA decides to move forward with a perchlorate regulation, then the proposed language for addressing MCL exceedances needs to be updated. As proposed, addressing perchlorate MCL exceedances and providing appropriate public notification in a timely manner would be difficult for states to enforce. Under the proposal, if the level of perchlorate exceeds the MCL, a confirmation sample must be collected within 2 weeks of notification of results and compliance with the MCL is determined based on the average of the initial and confirmation samples. However, if the average exceeds the MCL, Tier 1 public notification is required; which is within 24 hours after learning of the violation. Table 2 to 141.201 defines a Tier 1 public notice as "NPDWR violations and situations with significant potential to have serious adverse effects on human health as a result of short-term exposure." Therefore, EPA has proposed an acute MCL for perchlorate that is incongruous with the monitoring requirements of other Tier 1 contaminants. Allowing 2 weeks for an MCL confirmation sample but requiring 24-hour public notice is confusing and ill-advised. EPA would need to update the timeline for confirmation sample collection to follow other Tier 1 MCL exceedances. In addition, EPA did not propose updates to Subpart Q – Public Notification of Drinking Water Violations Table 1 to 141.202—VIOLATION CATEGORIES AND OTHER SITUATIONS REQUIRING A TIER 1 PUBLIC NOTICE restricting states' ability to enforce the Tier 1 requirement. As this is a federal regulation, Table 1 to 141.202 would need to be updated to include perchlorate MCL violations.
- **System Applicability:** Based on the above discussion on 24-hour public notice, it appears to be inconsistent to not have the perchlorate regulation apply to Transient Non-Community (TNC) systems. If EPA decides to move forward with a perchlorate regulation, the EPA should provide justification for not including TNCs.
- **Occurrence data:** Some states have concerns with using the UCMR1 monitoring data that is almost 20 years old. Some states believe this data under-represents national occurrence. Some states have discovered high levels of perchlorate in small systems that were not required to monitor during UCMR1. These small system detections occurred primarily due to aged hypochlorite. Seasonal systems where the hypochlorite

is stored in the off-season also detected high levels of perchlorate. Additionally, many seasonal systems are transient water systems that would not be required to monitor under the proposed rule although an acute MCL level is proposed.

- **Cost burden:** If EPA decides to move forward with a perchlorate regulation, this would be the first regulation with a negative cost-benefit. ASDWA recommends that EPA minimize the negative cost-benefit by evaluating options to reduce both the states' administrative burden (noting our previous comment on states' review of monitoring waivers) and the monitoring costs for states and water systems. As part of its evaluation of the perchlorate proposal, ASDWA asked states to estimate the number of staff hours required to read and understand the rule and to develop a primacy package for perchlorate, as well as a loading percentage for state staff wages. ASDWA received responses from 20 states and the average for both the hours and the loading percentage is in the range of EPA's estimates in its Information Collection Request (ICR) for the proposed perchlorate regulation. However, it should be noted that the primacy package for a potential perchlorate regulation would be relatively simple, as it is a single number for a single contaminant. The state burden for the development and approval of a primacy package (and for training of state staff) for a more complex rule like the Long-Term Revisions to the Lead and Copper Rule (LT-LCR) will be significantly higher.

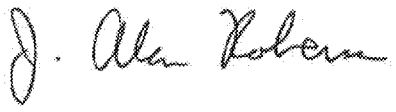
If EPA's final decision is a negative regulatory determination, other states may find there is an opportunity for significant public health protection and determine the need for a state-level standard. Such states would have to follow their own administrative processes for a state-level standard, and EPA should consider helping states with these processes. For example, EPA could help states with exposure assessments, evaluation of analytical methods, and/or treatment technology evaluations.

If EPA's final decision is a negative regulatory determination, then EPA needs to consider the Agency's options for the interim health advisory of 15 µg/L for perchlorate dating back to December 2008. Leaving this health advisory in place after a negative regulatory determination would create confusion for the water systems, primacy agencies and the public. While a health advisory is not a legally enforceable standard, a number is a number to the public. The expected or anticipated actions due to a water system having any water samples over any health advisory have shifted over the past four years, since the publication of health advisories for two cyanobacterial toxins in 2015. The publication of final health advisories in 2016 for perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) continued to add to the uncertainties for water systems and primacy agencies on what the appropriate actions should be when sample results are over the health advisories.

If EPA's final decision is a negative regulatory determination, then EPA needs to develop additional guidance and/or re-publicize existing technical information on the appropriate management of hypochlorite, as degradation of hypochlorite can contribute to perchlorate exposure. If EPA decides to move forward with a final regulation for perchlorate, ASDWA recommends that EPA discuss the potential exposure from hypochlorite degradation and the appropriate risk management in the final perchlorate regulation.

ASDWA appreciates the opportunity to comment on these important drinking water issues. If you have any questions about these comments or would like the states to provide additional input on the underlying issues, please feel free to email me at aroberson@asdwa.org or give me a call at (703) 812-9507.

Sincerely,



J. Alan Roberson, P.E.

PREFACE

This Public Health Goal (PHG) technical support document provides information on health effects from perchlorate in drinking water. PHGs are developed for chemical contaminants based on the best available toxicological data in the scientific literature. The PHG documents and the analyses contained in them provide estimates of the levels of contaminants in drinking water that would pose no significant health risk to individuals consuming the water on a daily basis over a lifetime. The PHG is a drinking water goal only; therefore, this document does not evaluate the safe levels of perchlorate in foods or other sources.

The California Safe Drinking Water Act of 1996 (Health and Safety Code, Section 116365) requires the Office of Environmental Health Hazard Assessment (OEHHA) to perform risk assessments and publish PHGs for contaminants in drinking water based exclusively on public health considerations. Section 116365 specifies that the PHG is to be based exclusively on public health considerations without regard to cost impacts. The Act requires that PHGs be set in accordance with the following criteria:

1. PHGs for acutely toxic substances shall be set at levels at which no known or anticipated adverse effects on health will occur, with an adequate margin of safety.

2. PHGs for carcinogens or other substances that can cause chronic disease shall be based upon currently available data and shall be set at levels that OEHHA has determined do not pose any significant risk to health.

3. To the extent the information is available, OEHHA shall consider possible synergistic effects resulting from exposure to two or more contaminants.

4. OEHHA shall consider the existence of groups in the population that are more susceptible to adverse effects of the contaminants than a normal healthy adult.

5. OEHHA shall consider the contaminant exposure and body burden levels that alter physiological function or structure in a manner that may significantly increase the risk of illness.

6. In cases of insufficient data to determine a level of no anticipated risk, OEHHA shall set the PHG at a level that is protective of public health with an adequate margin of safety.

7. In cases where scientific evidence demonstrates that a safe dose-response threshold for a contaminant exists, then the PHG should be set at that threshold.

8. The PHG may be set at zero if necessary to satisfy the requirements listed above.

9. OEHHA shall consider exposure to contaminants in media other than drinking water, including food and air and the resulting body burden.

10. PHGs published by OEHHA shall be reviewed every five years and revised as necessary based on the availability of new scientific data.

PHGs published by OEHHA are for use by the State Water Resources Control Board (SWRCB) in establishing primary drinking water standards (State Maximum Contaminant Levels, or MCLs). Whereas PHGs are to be based solely on scientific and public health considerations without regard to economic cost considerations, drinking water standards adopted by SWRCB are to consider economic factors and technological feasibility. Each standard adopted shall be set at a level that is as close as feasible to the corresponding PHG, placing emphasis on the protection of public health. PHGs established by OEHHA are not regulatory in nature and represent only non-mandatory goals. By federal law, MCLs established by SWRCB must be at least as stringent as the federal MCL if one exists.

In July 2014, responsibility for the state's drinking water regulatory program was transferred to SWRCB from the Calfornia Department of Public Health. References in this document to drinking water monitoring and regulation may cite either or both entities as appropriate.

Additional information on PHGs can be obtained at the OEHHA web site at www.oehha.ca.gov.

CONTENTS

PUBLIC HEALTH GOAL FOR PERCHLORATE IN DRINKING WATER

SUMMARY

The Office of Environmental Health Hazard Assessment (OEHHA) is publishing a Public Health Goal (PHG) of 1 part per billion (ppb) (equivalent to 1 microgram per liter [µg/L]) for perchlorate in drinking water. Perchlorate is an oxidizing chemical used in a variety of industrial processes. Perchlorate can occur in the environment either through industrial contamination or from natural sources. Perchlorate exposure in the U.S. is ubiquitous, mostly from ingestion of perchlorate in contaminated food or water. In a survey involving an essentially random sample of people from the U.S., perchlorate was detected in the urine of every one of the 2,820 subjects tested (Blount *et al.,* 2006).

Health Impacts from Perchlorate

For this PHG, OEHHA used decreased uptake of iodide by the thyroid gland as the key biochemical event for assessing the risks due to perchlorate toxicity. The primary action of perchlorate in humans is inhibition of iodide uptake into the thyroid gland. The function of the thyroid gland is the production of thyroid hormone. Iodide is a key component in the structure of thyroid hormone, and by blocking its uptake into the thyroid, perchlorate can potentially cause decreased production of this hormone.

Thyroid hormone is necessary for a variety of basic human physiologic functions, including controlling basal metabolic rates; protein, carbohydrate, and fat metabolism; protein synthesis; proper differentiation and development of cells, including neuronal cells; and the cognitive and physical development of the fetus, infant, and child. Evidence suggests that even small decreases in thyroid hormone levels may be associated with significant adverse effects, including altered cognitive development in children and increased cardiovascular risk factors in adults. Importantly, these changes have been seen at thyroid hormone levels that are within what have been traditionally defined as normal reference ranges, and have occurred in people without any other evidence of overt thyroid disease. These findings suggest that small changes in thyroid hormone levels may be associated with some increased risk of thyroid-related adverse outcomes.

There is a continuum in the possible health effects from perchlorate exposure resulting from its effects on the thyroid, and some susceptible groups or individuals may have perchlorate-related effects at exposures that are lower than those causing similar effects in healthy individuals. For fetuses, infants and children, there is the potential for abnormal growth and development. Of particular concern are effects on brain development. Decreases in thyroid hormone production in infants are related to decreases in IQ. Much of the knowledge on the potential effects of perchlorate comes from extensive data on iodine deficiency in humans.

OEHHA considers effects on thyroid hormone production and subsequent changes to be adverse. Iodide uptake inhibition is the key event that leads to other possible effects from perchlorate exposure. Prevention of iodide uptake inhibition prevents progression to the adverse health effects of perchlorate. The inhibition of iodide uptake by perchlorate has been clearly documented in humans. The National Academy of Sciences (NAS, 2005) deemed "inhibition of iodide uptake by the thyroid as the basis of the perchlorate risk assessment to be the most health-protective and scientifically valid approach." OEHHA agrees with this approach and used it in developing its original 2004 PHG for perchlorate.

The Greer *et al.* (2002) study was used to characterize perchlorate's inhibition of iodide uptake for both the current PHG and the 2004 PHG. It might be argued that the magnitudes of the effects seen in the Greer *et al.* (2002) study were relatively small, and might not be noticeable in otherwise healthy individuals. However, this ignores the impact of these effects on a population basis. Any downward shift in the mean level of the thyroid hormone T4 in a population could increase the number of people who fall into the range of T4 values that are associated with high risks of either subtle or overt thyroid-related disease and toxicity (Miller *et al.,* 2009).

The perchlorate PHG of 1 ppb is intended to help prevent any perchlorate-related decrease in iodide uptake by the thyroid that could lead to decreased thyroid hormone production and that could disrupt the important functions of this hormone.

Estimating the Acceptable Daily Dose for Perchlorate

The PHG was derived by first calculating an Acceptable Daily Dose (ADD). This is consistent with the approach taken by the NAS (2005). The ADD is defined as the estimated maximum daily dose that can be consumed by humans for an entire lifetime without toxic effects, and is similar in definition to the reference dose (RfD) used by the U.S. Environmental Protection Agency (U.S. EPA). The ADD for perchlorate was estimated using data from the human study by Greer *et al.* (2002). This is the same study used in developing OEHHA's 2004 perchlorate PHG, and by the NAS (2005) in developing its perchlorate reference dose.

Health Value from the Greer *et al.* Study

In the Greer *et al.* (2002) study, a daily oral dose of perchlorate was administered to groups of male and female volunteers for 14 days at doses of 0.007, 0.02, 0.1, or 0.5 mg/kg-day. Reductions in iodide uptake by the thyroid gland were seen at all four dose levels, with statistically significant reductions at the highest three doses. These results were plotted and dose-response relationships fitted to estimate the dose of perchlorate likely to cause a five percent decrease in iodide uptake. This dose was defined as the Benchmark Dose (BMD), and its lower 95 percent confidence limit was defined as the BMDL. This is the same method and data set used to establish the 2004 perchlorate PHG, and the BMD of 6.8 µg/kg-day and BMDL of 3.7 µg/kg-day are the same. The units µg/kg-day refer to micrograms (µg) of perchlorate ingested in one day per kilogram (kg) of body weight.

OEHHA used the BMD approach rather than the no-observed-effect level (NOEL) approach for the following reasons. OEHHA, like U.S. EPA, has chosen to use the BMD approach as the standard method in dose calculations, provided there are sufficient data to do so. As the U.S. EPA (2012, p. viii) notes, the BMD approach "involves dose-response modeling to obtain BMDs, i.e., dose levels corresponding to specific response levels near the low end of the observable range of the data, incorporates and conveys more information than the [NOAEL; no-observed-adverse-effect level] or [LOAEL; lowest-observed-adverse-effect level] process traditionally used for noncancer health effects." The NAS (2009, p. 129) in its review of U.S. EPA risk assessment practices similarly has recognized this as a refinement that makes better use of the dose-response evidence available than do calculations based on NOAELs.

The NOEL approach depends heavily on a single chosen dose level used in a study, and how closely it is placed relative to the next highest dose. The NOEL approach treats small and large studies the same, even though small studies, with their limited number of subjects, are less likely than large studies to find health effects at any given dose. In this case, the small group sizes in the Greer *et al.* (2002) study make it more difficult to detect an effect. For these reasons reliability of the NOEL approach can vary depending on the size of the study. In contrast, the BMD approach provides a systematic method for calculating a dose at a low specific effect level. The BMD approach uses all the dose-response evidence in the study, incorporates the shape of the dose-response curve, and takes into account the number of subjects in the study, thus providing a more reliable calculation. The advantages of using the BMD approach for this PHG are particularly important given the limited number of subjects that participated in the Greer *et al.* (2002) study.

Sensitive Populations

In the next step, the ADD of 0.37 µg/kg-day was calculated by dividing the BMDL by an uncertainty factor of 10. The NAS also used a 10-fold uncertainty factor in

developing its perchlorate reference dose (NAS, 2005). This uncertainty factor reflects the varying susceptibility of humans to perchlorate and was used because the Greer *et al.* (2002) study involved only healthy adult volunteers.

A fairly extensive body of evidence suggests that certain population subgroups may be much more susceptible to the effects of perchlorate than healthy adults. In reviewing the literature, OEHHA identified several reasons why infants, especially those that are born prematurely, are likely to have increased susceptibility to perchlorate. We also identified several other groups as likely having increased susceptibility, including fetuses, pregnant women, those with low intakes of iodine, and those exposed to other chemicals in food and water that, like perchlorate, also block iodide uptake into the thyroid.

The major change in the current PHG calculation relates to the updated information on infants as a sensitive population. OEHHA's review and updating of the perchlorate PHG considered the data from several human studies published after the 2004 PHG and the 2005 NAS review. These studies provided qualitative support for recognizing that infants are likely to be significantly more susceptible to perchlorate than healthy adults. Evidence for this includes the following:

1. New data suggest that many infants may not be receiving adequate iodine in their diets. In a study of nursing mothers in Boston, 47 percent of breast milk samples did not contain enough iodine to meet the infant iodine intake recommended by the Institute of Medicine (Pearce *et al.,* 2007). Perchlorate-related toxicity is likely to be greater in infants who are already deficient in iodine.
2. OEHHA's analysis of data from studies conducted in California and elsewhere provide evidence that thyroid hormone levels in infants were adversely affected by perchlorate at exposure levels that were much lower than the levels shown to cause no effects in healthy adults (Kelsh *et al.,* 2003; Brechner *et al.*, 2000; Buffler *et al.,* 2006; Steinmaus *et al.*, 2010; Li *et al.,* 2000a; Crump *et al.,* 2000).
3. Young infants have low stores of thyroid hormone (less than one day's worth, compared to several weeks' worth in adults) (van den Hove *et al.*, 1999). Because of these low stores, infants may be less able to tolerate transient periods of decreased iodide uptake and decreased thyroid hormone production compared to adults.
4. Human data suggest that perchlorate can interact with other contaminants to produce a greater effect than that caused by perchlorate alone (Blount *et al.*, 2006; Steinmaus *et al.*, 2007), and infants are exposed to these same contaminants.

In the 2004 PHG, an uncertainty factor of 10 was applied to address all sensitive groups (pregnant women, lactating women, thyroid compromised adults) except infants, where an uncertainty factor of 3 was used. However, given the evidence discussed above, the extent and ways infants are likely to be more susceptible to

perchlorate than healthy adults, and the fact that the Greer *et al.* (2002) study included only healthy adults, OEHHA has increased the uncertainty factor applied to infants from the factor of 3 used in the 2004 PHG to a factor of 10 in this updated PHG. This was one factor that resulted in the lowering of the updated PHG. The other factor driving the change in the PHG value is the use of updated drinking water intake rates for infants, described below.

Calculating the PHG

The ADD was then used to develop the PHG in the following two steps. First, the ADD was converted into an acceptable drinking water perchlorate concentration (in units of µg of perchlorate per liter (L) of drinking water). This was done by dividing the ADD by a drinking water intake rate expressed in terms of liters of water consumed per day per kilogram of body weight. The second step involves accounting for perchlorate intake from sources other than drinking water.

Water Consumption by Infants

The water consumption rate by infants is one of the factors that influence the final PHG. The recent analysis by OEHHA (2012) of data available from a large survey of food and beverage intake conducted by the U.S. Department of Agriculture shows that drinking water intakes per kilogram of body weight are higher in infants than previously thought. This means that infants are likely to have greater perchlorate exposure per kilogram of body weight for a given concentration of perchlorate in drinking water than was estimated in the 2004 PHG.

OEHHA used its new analysis and chose the 95th percentile drinking water intake rate instead of an average rate in order to protect the infant population, and not just those with average drinking water consumption. Infants who drink more water will have a greater exposure to perchlorate and thus may be at greater risk. In this case the bottle-fed infant will have the greatest intake of water and exposure to water contaminants.

The 95th percentile value of 0.237 L/kg-day for drinking water intake per body weight for infants aged 0-6 months (OEHHA, 2012) was used in the PHG calculations. For comparison, U.S. EPA (2009) typically assumes that infants and children drink 1 liter (L) per day and that they weigh 10 kilograms, that is 0.1 L/kg-day. Using the U.S. EPA value would result in a PHG of 2.7 ppb instead of 1 ppb.

Relative Source Contribution: Addressing Perchlorate Exposure from Other Sources

In the second step of the PHG calculation, an adjustment was made to account for perchlorate intake from sources other than drinking water. Because the ADD is the acceptable daily dose for all sources of perchlorate intake combined (i.e.,

food plus water), estimated intakes from food must be accounted for when developing a PHG for drinking water. This is a standard approach for developing drinking water criteria and is also required under Health and Safety Code Section 116365 (c)(1)(C)(iv). In OEHHA's review, it was determined that food was the only other significant source of perchlorate exposure in the large majority of people. Intake from food is accounted for by multiplying the ADD by the relative source contribution (RSC), defined as the fraction of the ADD (which incorporates perchlorate from food plus water) expected to come from water. Since infants were identified as a susceptible group, the amount of perchlorate expected to come from food was estimated using the median perchlorate levels in powdered infant formula reconstituted with perchlorate-free water (Schier *et al.*, 2010).

Based on these data, OEHHA calculated a RSC of 0.73. These two steps were used to develop an updated health-protective concentration (C) based on the following calculations: C = ADD × RSC ÷ drinking water rate = 0.37 µg/kg-day × 0.73 ÷ 0.237 L/kg-day = 1 µg/L, that is 1 ppb. Thus, the PHG for perchlorate in drinking water is 1 ppb.

Comparison with Other Agencies

In 2004 a PHG of 6 ppb was set for perchlorate, and the California Maximum Contaminant Level (MCL) for perchlorate was subsequently set at 6 ppb (Ting *et al.*, 2006). Currently, there is no federal MCL for perchlorate. The current OEHHA PHG of 1 ppb updates the PHG of 6 ppb set in 2004.

PHGs published by OEHHA are for use by the State Water Resources Control Board (SWRCB) in establishing primary drinking water standards, that is, the California MCLs. In developing the PHG for perchlorate, OEHHA's approach follows that used by the NAS (2005) to develop its reference dose in several key areas:

1. Both OEHHA and NAS identified the Greer *et al.* (2002) human study as the critical study for evaluating the effects of perchlorate.
2. Both OEHHA and NAS chose iodide uptake inhibition in the Greer *et al.* (2002) study as the key effect on which to base their calculations.
3. Both OEHHA and NAS noted that the subjects in the Greer *et al.* (2002) study were healthy adults and concluded that some people may be more susceptible to perchlorate than these healthy adult subjects. For this reason, both OEHHA and NAS applied an uncertainty factor of 10 to calculate a dose that would address inter-individual variability among humans and be protective of those who are likely to be sensitive to the effects of perchlorate.
4. Both OEHHA and NAS identified the same populations likely to be more sensitive to perchlorate exposure: fetuses, preterm newborns, infants, developing children, pregnant women, people who have compromised

thyroid function resulting from conditions that reduce thyroid hormone production, and people who are iodine-deficient.

There is only one substantive difference between the OEHHA and NAS analyses. The NAS used the no-observed-effect level (NOEL) approach. They determined that the NOEL was 0.007 mg/kg-day, the highest dose in the Greer *et al*. (2002) study that was not associated with a statistically significant response. OEHHA used the Benchmark Dose (BMD) approach and calculated a point of departure of 0.0037 mg/kg-day. As discussed above, the BMD method is a statistical method that is now widely recognized as a better approach because it incorporates more dose-response information from the study than the NOEL method (NAS, 2009; U.S. EPA, 2012).

From the NOEL, the NAS calculated a reference dose of 0.0007 mg/kg-day (the NOEL divided by the uncertainty factor of 10). OEHHA similarly calculated an ADD of 0.00037 mg/kg-day (the BMD-derived point of departure divided by the same10-fold uncertainty factor). Thus the two approaches differ by less than a factor of 2. The NAS did not take the next step to calculate an acceptable drinking water level for perchlorate.

Conclusion

In conclusion, the primary toxic mechanism of perchlorate is a reduction in iodide uptake into the thyroid gland. If severe enough, this can lead to reduced thyroid hormone production. Adequate supplies of thyroid hormone are vital for a variety of physiologic processes, and even small reductions in thyroid hormone have been associated with increased cardiovascular disease risk factors, abnormal fetal brain development, and altered childhood cognition. The purpose of this updated PHG of 1 ppb is to identify a level of perchlorate in drinking water that prevents perchlorate-related reductions in thyroidal iodide uptake and subsequent decreases in thyroid hormone production that may be associated with any of these adverse health effects.

1. INTRODUCTION

Purpose

The purpose of this document is to evaluate current scientific information on perchlorate in order to update the health-protective concentration estimate, or Public Health Goal (PHG), for perchlorate in drinking water. PHGs are based on a comprehensive analysis of information on the toxicology of drinking water contaminants, and are based solely on protection of public health without regard to cost impacts or other factors. PHGs for carcinogens are set at a *de minimis* risk level of one in a million (10^{-6}), assuming a lifetime of exposure to the chemical in the drinking water. PHGs for noncarcinogens are based on levels estimated to be without risk of any adverse effects for exposures up to a lifetime, to the general population as well as any significant identifiable sensitive subpopulations.

Perchlorate is a ubiquitous environmental contaminant. It is apparently formed by sunlight or lightning interacting with oxygen and chlorine in the atmosphere, and falls to the earth in rain (Dasgupta *et al.*, 2005; Mohan, 2010). Plants can accumulate perchlorate from the water they take up. Perchlorate is also released to the environment from its use in highway flares, fireworks and other explosives, and rocket fuel. People are primarily exposed to perchlorate through consumption of food and water.

Exposure to perchlorate may cause harmful health effects due to its competition with iodide for uptake into the thyroid gland. Iodide is used by the thyroid gland to make the thyroid hormones thyroxine and triiodothyronine (also known as T4 and T3). Decreased uptake of iodide can decrease production of thyroid hormone and impair normal metabolism and growth. Several other chemicals that people are commonly exposed to, such as nitrate, thiocyanate, and bromide, can also compete with iodide for uptake into the thyroid. Maintenance of normal production of thyroid hormone depends on the availability of iodide, obtained mostly from the diet, as well as the combined effects of the various competitors for iodide uptake.

This document represents an update of an earlier health risk assessment of perchlorate conducted by OEHHA that resulted in the publication of a PHG in 2004. This revision takes into account information which suggests that infants can be especially susceptible to perchlorate, along with pregnant women and their fetuses and those with iodine deficiencies. This revision also incorporates the higher drinking water consumption values described by OEHHA (2012) to be more protective of the entire population.

Chemical Profile

Chemical Identity

Perchlorate (ClO_4^-) is the most oxygenated member of a series of four anions made up of chlorine and oxygen. The anion has a charge of negative one, and can form an acid or a salt in combination with H^+ or another cation such as sodium, potassium or ammonium. Perchlorate salts are ionic, and dissociate completely when dissolved in water. This risk assessment is for the perchlorate anion in water, regardless of the cation.

Physical and Chemical Properties

Ammonium perchlorate (NH_4ClO_4), the salt used as an oxidizer in rocket propellants, is a white, crystalline solid. As ammonium perchlorate is the major source of most of the perchlorate that has been detected in drinking water sources in California and Nevada (U.S. EPA, 1998a), it is used as the model compound to illustrate some of the physical and chemical properties of perchlorate salts (Table 1).

Table 1. Physical and Chemical Properties of Ammonium Perchlorate (from HSDB, 2010)

Property	Value or Information
Molecular Weight	117.49
Color/Physical State	White orthorhombic crystals
Melting Point	130°C, starts to decompose at 439°C
Solubility in water	200 g/L at 25°C
Solubility in organic solvents	Soluble in methanol, slightly soluble in ethanol and acetone, almost insoluble in ethyl acetate, ether
Density	1.95 g/cm^3

Production and Uses

Ammonium perchlorate is used as an oxidizer in solid rocket propellant. Sodium perchlorate is used in slurry explosives, and potassium perchlorate is used in road flares and air bag inflation systems. The manufacture of perchlorate salts begins with the electrolysis of brine (sodium chloride in water) to first form sodium chlorate ($NaClO_3$) and then sodium perchlorate ($NaClO_4$). This is reacted with ammonium chloride to form ammonium perchlorate (NH_4ClO_4) and sodium chloride. The solution is cooled, and the ammonium perchlorate crystals are dried and packaged.

Ammonium perchlorate is mixed with metallic aluminum in a synthetic rubber base to make rocket fuel. This type of fuel is used in the Minuteman missile, which has been deployed in the United States since 1961. Perchlorate salts are also used as a component of air bag inflators, in nuclear reactors and electronic tubes, as additives in lubricating oils, in tanning and finishing leather, as a mordant for fabrics and dyes, and in electroplating, aluminum refining, rubber manufacture, and the production of paints and enamels (U.S. EPA, 2002).

Perchlorate has been used as a growth promoter in leguminous plants (Verteletskaya *et al.*, 1974; as cited in Von Burg, 1995), livestock (sheep and cattle) and poultry (Yakimenko *et al.*, 1981; as cited in Von Burg, 1995). Research from the former Soviet Union indicated that weight gains in livestock of 3 to 31 percent were obtained by addition of ammonium perchlorate to the feed. Feed expenditure was also reduced 7-18 percent. The optimum dose was estimated to be 2-5 mg/kg (Grayson, 1978). Weight gains in livestock may be secondary to hypothyroidism and decreased metabolic rates. This is most likely a non-nutritive effect associated with the inhibition of thyroid hormone production and subsequent hypothyroidism.

Perchlorate has no known nutritional use. In 1952, investigators observed that perchlorate displaces iodide from the rat thyroid (Wyngaarden *et al.*, 1952). Since then perchlorate has been widely used in laboratory studies on the thyroid to block entry of iodide into the thyroid, or to cause discharge of noncovalently bound iodide previously accumulated in the thyroid (Wolff, 1998).

Environmental Occurrence and Human Exposure

Perchlorate can apparently be formed by sunlight or lightning interacting with oxygen and chlorine in the atmosphere (Dasgupta *et al.*, 2005; Mohan, 2010). As perchlorate falls to the earth in rain, it can distribute at low levels throughout the environment, in both soil and water. Plants can accumulate perchlorate from the water they take up (U.S. EPA, 2001a; Jackson *et al.*, 2005; Sanchez *et al.*, 2005 a,b, 2008).

Perchlorate is also released to the environment from its use in highway flares, fireworks and other explosives, and rocket fuel. Perchlorate salts have been widely used as an oxidizer in solid propellants for rockets and missiles since the mid-1940s. Because of its finite shelf life, the propellant containing perchlorate has been periodically washed out of the United States' missile and rocket inventory to be replaced with a fresh supply (U.S. EPA, 1998a). As a consequence of this practice, large volumes of perchlorate have been disposed of since the 1950s. Some of this has leached into soil, and into aquifers used for drinking water. Perchlorate is highly mobile in aqueous systems and can persist for many decades under typical ground and surface water conditions (U.S. EPA, 1998a).

Air

Some unreacted perchlorate is occasionally released to the atmosphere during the launch of solid fuel rockets. Releases have also occurred as a consequence of open burning and detonation of old rocket fuel or surplus materials. No data were found on levels of perchlorate in ambient air.

Perchlorate dust can also be suspended in air, and can be inhaled by individuals working in areas where perchlorate is manufactured (Lamm *et al.*, 1999).

Soil

As a result of past disposal practices, including replacement of rocket fuel supplies noted above, soil and groundwater near the facilities that had been engaged in rocket fuel manufacturing and disposal are contaminated (U.S. EPA, 1998a). Releases to soil might also have occurred because of the past open burning and open detonation of perchlorate-containing material. Another way in which soil can become contaminated is by irrigation with perchlorate-contaminated water.

A report by TRC Environmental Corporation (1998) raised the concern that some chemical fertilizers may be contaminated with perchlorate. In the past, some fertilizers derived from Chilean caliche (a natural perchlorate source) were found to be contaminated with perchlorate. Since this discovery, the producer of Chilean caliche has changed its practice and eliminated the perchlorate contamination. U.S. EPA (2001b) tested a variety of fertilizers collected from representative sites around the nation and did not find perchlorate contamination to be a problem.

Water

Drinking water sources have become contaminated with perchlorate as a consequence of soil pollution in areas where solid rocket fuel has been manufactured, used, or disposed of. Perchlorate salts are soluble in water and once dissolved, perchlorate ion can persist in surface and ground waters for several decades (U.S. EPA, 1998a).

Until March 1997, the detection limit for perchlorate in water was rather high, at 400 µg/L (ppb). In March 1997, California Department of Health Services (DHS), now the California Department of Public Health (DPH), developed a more sensitive analytical procedure, using ion chromatography, and achieved a detection limit in the 4-5 ppb range (DHS, 2000). Shortly thereafter, the new technology was adopted by a number of commercial laboratories. U.S. EPA Method 314.0 (Federal Register, 2000) now exists for analysis of perchlorate in water and has a detection limit as low as 0.5 ppb.

Since March 1997, California DPH (and now SWRCB) has reported measurements of perchlorate concentrations in thousands of drinking water sources and wells throughout the state. Between 2010 and 2013, perchlorate concentrations above 4 ppb were reported in 248 drinking water sources in California (Table 2).

Urbansky *et al.* (2000) analyzed samples of eight domestic brands and eight imported brands of bottled water and did not find perchlorate (with a detection limit of 5 ppb) in any of the samples.

Blount *et al.* (2010) measured perchlorate concentrations in tap water samples collected from 3,262 subjects from the 2005-6 United States National Health and Nutrition Examination Survey (NHANES), and reported a geometric mean of 0.714 µg/L (95% confidence interval (CI), 0.551-0.998 µg/L). Using these measurements, and 24-hour recall data on tap water consumption, the authors estimated a median perchlorate intake of 9.11 ng/kg-day from tap water for U.S. men and women over age 12. The relevance of these findings to California, especially to those areas with documented perchlorate contamination, is unknown, and estimated intakes in potentially susceptible groups such as infants were not reported.

Food

Plants take up perchlorate from water, and probably also from fertilizers which contain perchlorate (U.S. EPA, 2001a; Trumpolt *et al.*, 2005). In a greenhouse study, U.S. EPA researchers watered lettuce plants with one of five different concentrations of perchlorate (0.1, 0.5, 1.0, 5.0, and 10.0 µg/mL) for a period of 90 days following planting. They found perchlorate levels rose steadily over the first 50-60 days, and then generally leveled off. The amount of perchlorate detected in the leaves correlated with the water concentration. At about 50 days into the study, the lettuce irrigated with 10.0 µg/mL (ppm) perchlorate had a perchlorate content of about 300 µg/g on a wet weight basis (U.S. EPA, 2002).

Table 2. Reported Perchlorate Detections in California 2010-2013 (from SWRCB, 2014) [a, b]

	Peak ≥ 4 µg/L		Peak ≥ 6 µg/L		
County	No. of Sources	No. of Systems	No. of Sources	No. of Systems	Highest Peak (µg/L)
Contra Costa	1	1	1	1	7.9
Fresno	1	1	-	-	4.5
Kern	2	2	1	1	14
Los Angeles	98	31	68	21	108
Monterey	1	1	-	-	4.8
Orange	11	7	3	2	9
Riverside	49	8	38	8	68
Sacramento	2	1	2	1	13
San Bernardino	57	19	37	16	94
San Diego	10	2	8	2	9.9
Santa Barbara	1	1	-	-	4.6
Santa Clara	5	4	3	3	10
Sutter	3	3	1	1	10
Tulare	6	3	5	3	20
Ventura	1	1	-	-	5.2
TOTAL	248	85	167	59	-

[a] Data for perchlorate were extracted from the water quality monitoring database (http://www.waterboards.ca.gov/drinking_water/certlic/drinkingwater/EDTlibrary.shtml).

[b] Where raw and treated samples or other results indicate more than one sampling point for the same source, they are counted as coming from a single source. All detections greater than the detection limit for purposes of reporting (DLR), however, are available here: http://www.waterboards.ca.gov/drinking_water/certlic/drinkingwater/Documents/Perchlorate/perchloratedetects2010-2013forweb.xls.

Scientists at Texas Tech University (Lubbock, Texas) developed sensitive methods for assaying perchlorate in biological samples and reported perchlorate accumulation in a variety of crops as well as in animals, trees and aquatic plants (Smith *et al.,* 2001, 2004; Tan *et al*., 2004; Yu *et al*., 2004; Jackson *et al*., 2005). Concentration factors well over 100-fold, compared to the concentration in the water, were reported in some plants. Sanchez *et al*. (2005a,b) showed that perchlorate accumulated in lettuce and other leafy vegetables when grown with

Colorado River water contaminated with perchlorate at low ppb levels. Later studies by the same workers documented uptake in a wider variety of crops (Sanchez *et al.*, 2006, 2008).

In 2004-5, the U.S. Food and Drug Administration (U.S. FDA) measured perchlorate concentrations in many different types of foods. Results for 27 foods and beverages collected from areas where perchlorate was known to contaminate drinking water were reported (U.S. FDA, 2009). Multiple assays were conducted on each product, for a total of 775 results. Reported average values ranged from 0.15 ppb (µg/L) in potatoes (set at one-half the limit of detection, since all values were non-detect) to 92.4 ppb in "greens." Shrimp was second-highest, at 19.83 ppb. Cow's milk averaged 5.81 ppb.

Using food consumption estimates from the U.S. Department of Agriculture's Continuing Survey of Food Intake by Individuals (CSFII 1994-96 and 1998 Supplemental Children's Survey), U.S. FDA estimated dietary perchlorate consumption for various population groups. Mean perchlorate intake of persons aged 2 years and above was estimated to be 0.053 µg/kg-day. The estimated mean intakes for children aged 2-5 years, and for females aged 15-45 years, were 0.17 and 0.037 µg/kg-day, respectively. The estimated 90th percentile intakes were 0.12 µg/kg-day for all people aged 2 years and older; 0.34 µg/kg-day for children aged 2-5 years; and 0.074 µg/kg-day for females aged 15-45 years.

More recently, U.S. FDA has included perchlorate analysis in its Total Diet Study, which involves a periodic analysis of 285 foods selected to be representative of the total U.S. diet. As reported by Murray *et al.* (2008), food products were sampled in 2005-2006. Estimates of perchlorate intake were made using the CSFII data as described above. Upper and lower bound consumption estimates for various population groups are shown in Table 3. These perchlorate exposure estimates tend to be higher than the earlier FDA estimates, but they cover more foods.

There are concerns that breast milk may represent an exposure pathway for infants. In a study reported by Yu (2000), groups of female rats were treated with perchlorate in drinking water at 0, 0.01, 0.1, 1, and 10 mg/kg-day throughout gestation and lactation. On postnatal day 10, the rats were milked. Yu found the levels of perchlorate in milk were about twice as high as the corresponding levels in maternal serum across all doses, suggesting that perchlorate is actively sequestered into milk. Clewell *et al.* (2003) reported that perchlorate was indeed transferred to the pup through suckling as perchlorate was detected in milk, as well as in the neonate serum, gastrointestinal contents, and skin.

Human mammary gland during lactation has been shown to express the sodium-iodide symporter (NIS), the protein responsible for moving iodide into the thyroid and, in this case, into breast milk. The mammary gland may have the capability to actively secrete perchlorate into the breast milk (Vayre *et al.*, 1999; Tazebay *et*

al., 2000). Another concern is that iodide in breast milk is necessary for thyroid hormone synthesis by the newborn. Perchlorate inhibits the NIS in the lactating mammary gland and can interfere with the secretion of iodide into breast milk. This reduction in iodide transfer has been seen in cows and goats (Howard *et al.*, 1996; Lengemann, 1973; Mountford *et al.*, 1987).

Rice *et al.* (2007) analyzed the relationship between perchlorate in feed given to dairy cows and the resulting levels in milk. They reported that significant perchlorate exposures occurred from perchlorate in corn silage, alfalfa, and grass. Sanchez *et al.* (2008) also showed that perchlorate in alfalfa makes a major contribution to perchlorate levels in the milk of dairy cows.

Table 3. Estimated Perchlorate Intakes from U.S. FDA's Total Dietary Survey: Results for 2005–2006 (as reported in U.S. EPA, 2008b)

Population group		Perchlorate intake from food µg/kg-day	
		Lower-bound	Upper-bound
Infants	6-11 mo.	0.26	0.29
Children	2 yr.	0.35	0.39
Children	6 yr.	0.25	0.28
Children	10 yr.	0.17	0.20
Teenage Girls	14-16 yr.	0.09	0.11
Teenage Boys	14-16 yr.	0.12	0.14
Women	25-30 yr.	0.09	0.11
Men	25-30 yr.	0.08	0.11
Women	40-45 yr.	0.09	0.11
Men	40-45 yr.	0.09	0.11
Women	60-65 yr.	0.09	0.10
Men	60-65 yr.	0.09	0.11
Women	70+ yr.	0.09	0.11
Men	70+ yr.	0.11	0.12

Kirk *et al.* (2005) analyzed perchlorate concentrations in 47 different samples of dairy milk from 11 different states and 36 human milk samples from lactating women from 18 different states. Detectable levels of perchlorate were found in all but one of the samples tested. The mean perchlorate concentration in the breast milk samples was 10.5 µg/L. Iodine concentrations in milk were inversely correlated with perchlorate concentrations, but only in the six samples with perchlorate concentrations above 10 µg/L (coefficient of variation (R^2) > 0.9). In a later study, Kirk *et al.* (2007) measured perchlorate levels in 10 lactating women in six breast milk samples per day per woman for three days. The mean

perchlorate concentration was 5.8 µg/L (standard deviation (SD) ± 6.2 µg/L). Considerable variability was seen both among and between individuals.

Pearce *et al.* (2007) measured breast milk perchlorate levels in 49 women from the Boston area and in 17 different infant formulas. Perchlorate was detectable in all 49 breast milk samples tested and in all 17 infant formula samples tested. The median breast milk perchlorate concentration was 9.1 µg/L. This was about 3 times higher than the median perchlorate concentrations in the urine samples of these women. There was no correlation between breast milk iodine and perchlorate concentrations (R^2 = 0.05, p = 0.1), and no correlation in those women with breast milk perchlorate concentrations above 10 µg/L. The median breast milk iodine concentration was fairly low (median = 155 µg/L; range, 2.7 - 1968) and the authors estimated that 47 percent of the breast milk samples did not contain enough iodine to meet the infant iodine intake recommended by the Institute of Medicine.

Dasgupta *et al.* (2008) measured perchlorate, thiocyanate, and iodine in the urine and breast milk of 13 breastfeeding women. The mean breast milk perchlorate concentration was 9.3 µg/L (SD ± 7.5 µg/L). Selectivity factors were determined for each chemical based on the relative excretion of each in breast milk and urine. Total perchlorate excretion was based on urinary and breast milk excretion only and possible excretion via other pathways was ignored. The median fraction of total excretion in the milk for perchlorate, thiocyanate, and iodine were 0.541, 0.053, and 0.177. The selectivity factors for perchlorate over iodide transport, and thiocyanate over iodide transport, were 3.14 and 0.27, respectively. The authors note that these transport selectivities are an order of magnitude lower than those indicated in *in vitro* studies. The authors did not specifically report a correlation coefficient for the relationship between breast milk iodine and perchlorate concentrations but did note that in their plot of these data (their Figure 3) that there were no subjects in the high iodine-high perchlorate quadrant.

More recently, Valentín-Blasini *et al.* (2011) measured perchlorate in urine samples from 92 infants ages 1-377 days and estimated perchlorate intake doses based on these measurements. The median estimated intake was 0.160 µg/kg-day. Of the 205 individual dose estimates (multiple urine samples were collected from each subject), 9 percent exceeded the NAS (2005) reference dose of 0.7 µg/kg-day. Breast-fed infants had a higher estimated perchlorate exposure dose (geometric mean = 0.220 µg/kg-day) than infants consuming cow milk-based formula (geometric mean = 0.103 µg/kg-day, p < 0.0001) or soy-based formula (geometric mean = 0.027 µg/kg-day, p < 0.0001).

Kirk *et al.* (2013) used data on daily water intake, daily urine volume, predicted daily milk volume, and perchlorate concentrations in water, urine, and breast milk samples from 13 lactating women in Texas to estimate average daily exposure to perchlorate from food and water. The amount of perchlorate from water was estimated by multiplying the amount of daily water intake from each water source

used by the subject by the perchlorate concentration in samples of that water source and summing the results across all water sources. The amount of perchlorate from non-water sources (presumably mostly food) was then estimated by subtracting the estimate of exposure from water from the total amount of perchlorate excreted in urine and breast milk. The mean urinary perchlorate concentration was 3.6 µg/L, with a mean estimated daily urinary perchlorate excretion of 5.8 (±5.3) µg. Total excretion of perchlorate in breast milk was not provided, although based on perchlorate milk concentrations and typical milk consumption rates in infants the authors estimated that the average daily transfer of perchlorate to infants through breast milk was 12.87 (±8.99) µg. Using urine and breast milk perchlorate excretion rates, the mean maternal daily dose of perchlorate was estimated to be 0.186 µg/kg-day with an estimated 0.173 µg/kg-day (93 percent) coming from non-water sources. Importantly, mean perchlorate water concentrations in this population were low (0.46 µg/L ±1.11) so these data are likely not relevant to subjects who live in areas with greater perchlorate contamination in drinking water.

Huber *et al.* (2011) used urinary concentrations of perchlorate measured in the 2001-2 NHANES and drinking water perchlorate concentrations from the U.S. EPA Unregulated Contaminant Monitoring Rule (UCMR) database to estimate the possible amount of perchlorate exposure due to food and water in U.S. adults and children ages 6 and older. The UCMR database included perchlorate water concentrations in a "near census" of 3,086 large public water systems (those serving >10,000 people) and 797 representative small public water systems, measured between 2000 and 2005. NHANES is a large, essentially nationally representative survey performed in the U.S. by the Centers for Disease Control and Prevention. Residential location for NHANES subjects was only available to the researchers on a county-level basis. Subjects in NHANES with urinary perchlorate measurements were divided into one of three bins. Bin I (n=320) included subjects residing in counties where at least one water system had at least one UCMR water perchlorate measurement above the detection limit of 4 µg/L. Bin III (n=2,059) included subjects residing in counties where a drinking water system had been sampled for perchlorate but all measurements were below the detection limit. Bin II (n=325) included subjects who had no UCMR measurements for a water system in the county in which they resided. Estimates of 24-hour perchlorate intake were calculated for all subjects using single spot urinary perchlorate concentrations with adjustments for urinary creatinine. Estimates in Bin III subjects were assumed to represent typical daily exposure from food, while the difference in estimates between Bins I and III was assumed to represent typical daily exposure from water. Overall, the mean estimates were 0.081 µg/kg-day in Bin III (food only) subjects and 0.101 µg/kg-day in Bin I subjects (food + water), and the authors estimated that about 19.7 percent of perchlorate exposure in subjects from exposed counties came from water. Estimates of intakes from water in specific age groups ranged from 2.1percent for ages 6-11 to 25.6 percent for ages 12-19. Overall, these data suggest that food is typically the predominant source of perchlorate for most people in the U.S. Potential weaknesses included the fact that not all water systems were

measured (i.e., many smaller public water systems and all private wells were not measured), the potential impact of fasting was not accounted for, data on the amount of water consumption subjects had from any particular water source was not incorporated, and no estimates were available for children under age 6. Also, the detection limit for perchlorate at the time the water sources were measured was 4 µg/L, so there is little information in this study on the impacts of lower exposures (i.e., those above zero but below 4 µg/L). In addition, many counties have multiple water systems with highly variable perchlorate levels. As such, it is likely that many people in a county with a single positive drinking water perchlorate measurement will actually be drinking water from a system with very low or no perchlorate. The inclusion of these lower exposure people in Bin I would lead to underestimates of the true intake of perchlorate from drinking water. Because of these weaknesses, the specific contribution of perchlorate from water in people who have elevated levels of perchlorate in their drinking water cannot be accurately estimated using the data from this study.

2. METABOLISM AND PHARMACOKINETICS

Absorption

Test data from human studies indicated that perchlorate is readily absorbed from the gastrointestinal tract and excreted primarily via the urine. Eichen (1929; as cited in Stanbury and Wyngaarden, 1952) orally administered 1-2 g perchlorate to patients and recovered 70 percent of the dose in the urine in 12 hours and 85-90 percent in 24 hours. In a similar experiment, two human subjects each drank a solution of 794 mg of sodium perchlorate dissolved in 100 mL of water (Durand, 1938). Fifty percent of the administered dose was recovered in the urine by five hours and 95 percent in 48 hours. These human data suggest absorption of perchlorate through the oral route is virtually complete.

Besides the thyroid, the sodium-iodide symporter (NIS) appears to be expressed and active in mammary gland, salivary glands, gastric mucosa, and placenta (Vayre *et al.*, 1999; Tazebay *et al.*, 2000; de la Vieja *et al.*, 2000; Mitchell *et al.*, 2001). These transport systems exhibit functional similarities with their thyroid counterpart and may play a role in the absorption of iodide into the body. Because perchlorate is completely ionized in aqueous systems, its permeability through intact skin is expected to be limited (U.S. EPA, 1998a). Inhalation exposure during showers is considered possible but not likely to be an important route of exposure. This is because the droplets produced in showers are generally too large to be inhaled. Exposure to vapors of the chemical via the inhalation route is expected to be negligible because of the low vapor pressure of perchlorate salts at room temperature. However, inhalation of airborne perchlorate particles could be an important exposure route in occupational settings. Lamm *et al.* (1999) studied a group of workers in a perchlorate production plant and reported that there was a correlation between airborne perchlorate dust concentration and the amount of perchlorate excreted in urine.

Distribution

Anbar *et al.* (1959) injected white rats and rabbits intraperitoneally with radiolabeled potassium perchlorate (approximately 3-14 mg per animal) and measured the specific activity per gram of tissue in various organs from 30 minutes to 12 hours post administration. The ratio of the specific activity of perchlorate in thyroids versus the specific activity in blood reached a limiting value of 4.3 ± 0.3 in both rats and rabbits, at about 6 hours after the injection. These data demonstrate that the thyroid of these species concentrates perchlorate ions. There were also indications that perchlorate is retained in the salivary gland and testes.

Chow *et al.* (1969) measured perchlorate uptake using radiolabeled perchlorate in male Sprague-Dawley rats. Rats were injected with 0.1, 0.2, or 5.0 meq/kg of perchlorate (14, 28, or 690 mg/kg, respectively) two hours prior to sacrifice. At

the low and middle doses, radiolabeled perchlorate concentrations in the thyroid were higher than those in the blood. At the high dose, perchlorate concentrations in the thyroid and blood were about the same. In a similar study, rats were exposed to 0.69, 1.4, 2.8, 6.9, or 14 mg/kg of perchlorate. The apparent accumulation of perchlorate in the thyroid, as reflected by the thyroid/blood ratio (which ranged from 31.1 to 2.5), was found to be inversely related to the perchlorate dose (U.S. EPA, 2002).

Chow and Woodbury (1970) also studied perchlorate accumulation by the thyroid. They administered perchlorate by intraperitoneal injection at 0.69, 14, or 280 mg/kg to groups of male Sprague-Dawley rats. The treated rats were sacrificed at 0.033, 0.067, 0.13, 0.2, 0.5, 1.0, 2.0, and 4.0 hours after dosing. The amount of perchlorate accumulation in the thyroid compared to that in the plasma was highest at the lowest dose. At the higher doses (at or above 14 mg/kg), the level of perchlorate in the thyroid was lower than in the plasma.

It has been shown that perchlorate inhibits iodide transport into the thyroid. Thyroid tissues can also concentrate several related monovalent anions. Measurement of the ability to be concentrated by thyroid tissues, or to inhibit iodide transport, has resulted in the following potency series for monovalent anion-based inhibition of iodide transport in thyroid slices: $TcO_4^- \geq ClO_4^- > ReO_4^- > SCN^- > BF_4^- > I^- > NO_3^- > Br^- > Cl^-$ (Wolff, 1964; as cited in Wolff, 1998). These relative potencies are based on *in vitro* data and high anion concentrations. It is not clear whether they also apply to *in vivo* scenarios, real-life human situations, or lower environmentally relevant exposure levels. Anbar *et al.* (1959) showed that the inhibition of iodide transport by perchlorate is a truly competitive process. They intraperitoneally injected ^{36}Cl-labeled perchlorate and iodide ions in various concentrations to groups of rats and found that either iodide or perchlorate could inhibit the accumulation of the other anion by the thyroid (Table 4).

Recently, the apparent accumulation of perchlorate by the thyroid of rodents has been disputed. Citing *in vitro* electrophysiological data, de la Vieja (2000) suggested perchlorate acts as a blocker of NIS, but it is not translocated via NIS into the cell. De la Vieja (2000) theorized that because ^{36}Cl chlorate (ClO_3^-) is a byproduct of the reaction employed to chemically synthesize ^{36}Cl perchlorate for the uptake study, it is possible that ^{36}Cl chlorate, rather than perchlorate, accounts for the measured radioactivity, given that chlorate is readily translocated via NIS into the cell.

Table 4. The Ratio between Concentrations of Iodide and Perchlorate Ions in the Thyroid (from Anbar *et al.*, 1959)

Iodide dose (mmol)	Perchlorate dose (mmol)	Ratio[a] I^-/ClO_4^-		
		60 min	120 min	360 min
0.14	0.028	4.7	6.9	3.3
0.14	0.14	2.1	2.7	2.2
0.028	0.14	0.53	0.58	0.67

[a]Ratio = concentration of iodide in thyroid / concentration of perchlorate in thyroid.

Goldman and Stanbury (1973) administered ^{36}Cl-labeled potassium perchlorate to male Sprague-Dawley rats by intraperitoneal injection (approximately 40 μg stable perchlorate per injection). The rats were maintained on a low iodine diet for 4-5 weeks prior to perchlorate administration. The level of perchlorate in the thyroid peaked at four hours after administration, then declined to approximately five percent of its peak at 96 hours. The decay followed an exponential function with a half-life of 20 hours. When the levels of radioactivity in the serum and the urine are plotted against time, they also followed an exponential function with a half-life of approximately 20 hours. Goldman and Stanbury (1973) also showed that most of the administered perchlorate was excreted in the urine. The retention of the radiolabel in selected tissues 96 hours after the administration of perchlorate is shown in Table 5.

There are also data indicating that perchlorate can pass through the placenta and affect the fetal thyroid. Thyroid enlargement and reduction of thyroidal iodide uptake have been detected in fetuses of laboratory animals exposed to perchlorate (see the discussion in the Developmental and Reproductive Toxicity section.)

Selivanova and Arefaeva (1986) administered a single oral dose of perchlorate to rats and observed a two-phase biological decay curve. The first biological half-life ranged from 1-2 hours and accounted for a calculated 96 percent of the dose. The second-phase half-life, which accounted for only four percent of the administered dose, ranged from 72 to 80 hours. Yu *et al.* (2000) injected perchlorate intravenously at doses of 0.01, 0.1, 1, and 3 mg/kg to male Sprague-Dawley rats and monitored the serum concentration of perchlorate over time. The estimated early- and terminal-phase half-lives of perchlorate were 2-3 hours and 12-26 hours, respectively.

Table 5. Percent Dose of ^{36}Cl/g Tissue 96 Hours after Intraperitoneal Injection of ^{36}Cl-perchlorate (from Goldman and Stanbury, 1973)

Organ	Percent dose/g tissue[a]
Thyroid	0.142 ± 0.1
Kidney	0.125 ± 0.09
Spleen	0.098 ± 0.03
Liver	0.048 ± 0.04
Brain	Background

[a]Mean ± standard deviation; each value represents five animals.

The differences in biological half-lives of perchlorate in rats in the studies above (Goldman and Stanbury, 1973; Selivanova and Arefaeva, 1986; Yu *et al.*, 2000) are partly due to the three different routes of administration. The difference may also be explained by the fact that the rats in the study reported by Goldman and Stanbury (1973) had been maintained on a low iodine diet for 4-5 weeks before the administration of perchlorate.

Metabolism

There are data to suggest that perchlorate is not metabolized in humans (Anbar *et al.*, 1959). Four patients were orally administered 200 mg of radiolabeled perchlorate (5 μCi), double labeled with ^{36}Cl and ^{18}O. The perchlorate was excreted unchanged in the urine with the two labels (^{36}Cl and ^{18}O) remaining associated in the same molecule. The results also showed that there was no reduction of perchlorate *in vivo*, as there was very little radioactivity associated with Cl^- and ClO^{3-} ions in urine.

Excretion

As described above, 95 percent of a dose of sodium perchlorate administered orally to human subjects was eliminated in the urine by 48 hours after administration (Durand, 1938). Lamm *et al.* (1999) monitored urinary perchlorate levels of two workers during three days with measurable occupational perchlorate exposure and during the subsequent three days without known perchlorate exposure. The perchlorate body burden, as measured using urinary perchlorate concentrations, increased over the three days of work exposure, with decreases between the 12-hour work shifts. The elimination of perchlorate after the last exposure period appeared to follow a first-order kinetics pattern. The average perchlorate elimination half-lives measured for the two workers were 7.9 and 8.2 hours.

Greer *et al.* (2002) administered oral doses of perchlorate in water to human volunteers and estimated half-life values ranging from 6.0 to 9.3 hours, with an

average value of 8.1 hours. These are similar to those reported in Lamm *et al.* (1999).

Selivanova and Arefaeva (1986) administered a single oral dose of perchlorate to rats, rabbits, and calves at 2, 20, 200, and 600 mg/kg in a single oral dose. They reported that in all cases, little or no perchlorate could be detected in the blood after 72 hours. A majority of the administered perchlorate was excreted in the urine; the feces excreted $\leq$ 8.5 percent. Yu *et al.* (2000) injected perchlorate intravenously to rats at doses of 0.01, 0.1, 1, or 3 mg/kg and reported that between 72 percent and 97 percent of the administered dose was excreted in the urine over a 24-hour period.

3. ADVERSE EFFECTS OF THYROID HORMONE AND IODINE DEFICIENCY

The most important and early effect of perchlorate exposure is its effect on reducing iodide uptake by the thyroid. Significant reduction in iodide uptake can lead to decreased thyroid hormone production. For this reason, this chapter reviews studies of the adverse health effects of iodine deficiency and decreased levels of thyroid hormone. This discussion is preceeded by a brief review of normal thyroid physiology.

Thyroid Physiology

The principal hormones secreted by the thyroid are thyroxine (T4) and triiodothyronine (T3). Iodide is a key component of both. While T4 is produced only by the thyroid gland, about 80 percent of T3 is formed outside the thyroid by deiodination of T4. T4 and T3 influence the growth and maturation of tissues, cell respiration and total energy expenditure, and the turnover of essentially all substrates (including carbohydrates, cholesterol, and proteins), vitamins, and hormones (including the thyroid hormones themselves).

The major components of thyroid hormone are iodide and tyrosine. Tyrosine is generally not the rate-limiting component. Iodine is a trace element, and its uptake into the thyroid can be rate-limiting in thyroid hormone production. Ingestion is the main route of iodine intake. Once ingested, iodine is reduced to iodide (I^-) in the gastrointestinal tract and is readily absorbed into the bloodstream.

Thyroid tissue has a special ability to selectively concentrate iodide from the blood where the concentration is usually very low. The thyroid can actively transport iodide into the thyroid such that the iodide concentration in the thyroid can be several hundred-fold higher than concentrations outside the thyroid. Such concentrations are presumably required to promote efficient thyroid hormone production and patients lacking the ability to concentrate iodide have goiters and are hypothyroid (Wolff, 1998). The molecule that is responsible for transport of iodide into the thyroid is called the sodium-iodide symporter (NIS). The structure and regulation of NIS have been characterized (de la Vieja *et al.*, 2000). Recently mouse NIS has been cloned and transferred into normally non-iodide-transporting cells, and these cells show perchlorate-sensitive iodide uptake capability (Perron *et al.*, 2001). These researchers also found evidence to indicate that the NIS is present in tissues other than the thyroid, including the stomach, lactating mammary gland, small intestine, skin, and brain.

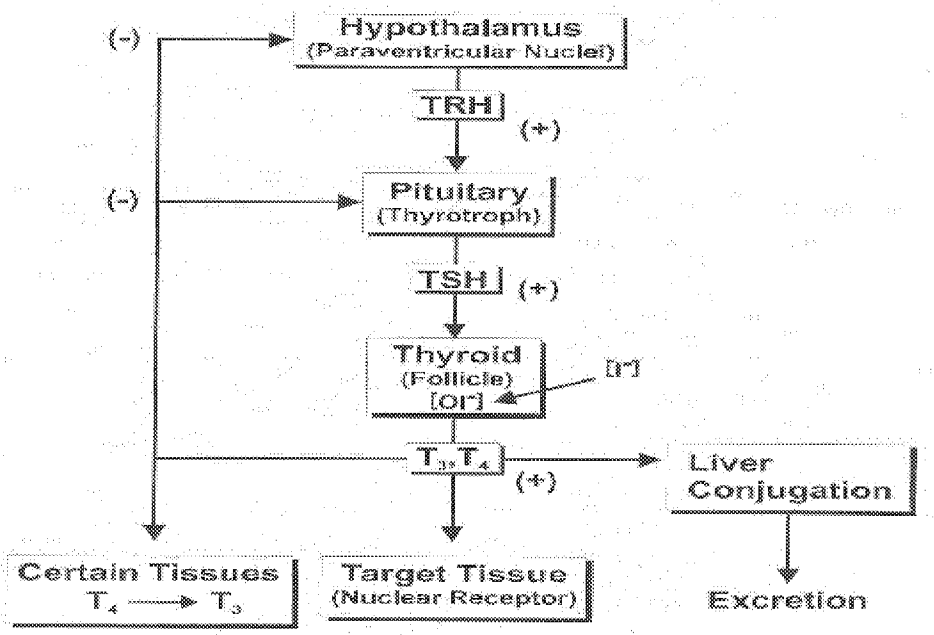
In humans, a majority of T4 and T3 in plasma is bound to proteins. In normal plasma, the T4 protein binding distribution is: 80 percent to thyroxine-binding globulin, 15 percent to transthyretin, and 5 percent to albumin and lipoproteins. For T3, the distribution is 90 percent bound to thyroxine-binding globulin and the

rest to albumin and lipoproteins, with little binding to transthyretin. Very small proportions of T4 and T3 are free (not protein bound) in plasma, 0.03 and 0.3 percent, respectively. Only the free hormone enters cells, exerts its biologic action, and determines thyroid physiologic status (Dillmann, 2000).

Control of T4 and T3 concentrations in blood is mainly regulated by a negative feedback loop involving three organs: the thyroid gland, which produces thyroid hormones; and the pituitary gland and hypothalamus, which respond to and help maintain optimal levels of thyroid hormones (Figure 1). When levels of thyroid hormone decline, the hypothalamus secretes thyrotropin-releasing hormone (TRH), which stimulates the pituitary to produce thyroid-stimulating hormone (TSH), which then prompts the thyroid gland to produce T4 and T3. The stimulated thyroid actively transports iodide into the thyroid gland, and then incorporates the iodide into thyroid hormone molecules. T4 and T3 are metabolized in the liver and other tissues. Some thyroid hormone derivatives are excreted in the bile, and some of the iodide in them is reabsorbed. Cells in the hypothalamus and pituitary gland respond to circulating levels of thyroid hormones, i.e., when hormone levels are high, there is a signal to reduce the output of TRH and TSH. Similarly, when thyroid hormone levels are low, the pituitary is prompted to release more TSH, which stimulates the thyroid to increase thyroid hormone output. This negative feedback loop helps the body to respond to varying demands for thyroid hormone and to maintain hormone homeostasis. Circulating T4, T3, and TSH can readily be measured in the serum of experimental animals and humans and serve as biomarkers of exposure and effect of agents that disrupt thyroid-pituitary status (U.S. EPA, 1998a, and 1998b; Hill *et al.*, 1989).

In mammals, when demands for more thyroid hormone are small, existing thyroid follicular cells can meet the demand. With increased need, as a result of certain chemical exposures or chronic iodine deficiency, the thyroid responds by increasing the size (hypertrophy) and number (hyperplasia) of thyroid follicular cells to enhance hormone output. With continued TSH stimulation, there is actual enlargement of the thyroid gland (goiter) and, at least in rodents, neoplasia of the thyroid follicular cells could eventually occur. Since TSH-producing pituitary cells are also stimulated, they too sometimes undergo hyperplasia and neoplasia (U.S. EPA, 1998b).

Figure 1. Hypothalamic-Pituitary-Thyroid Axis (from U.S. EPA, 1998b)

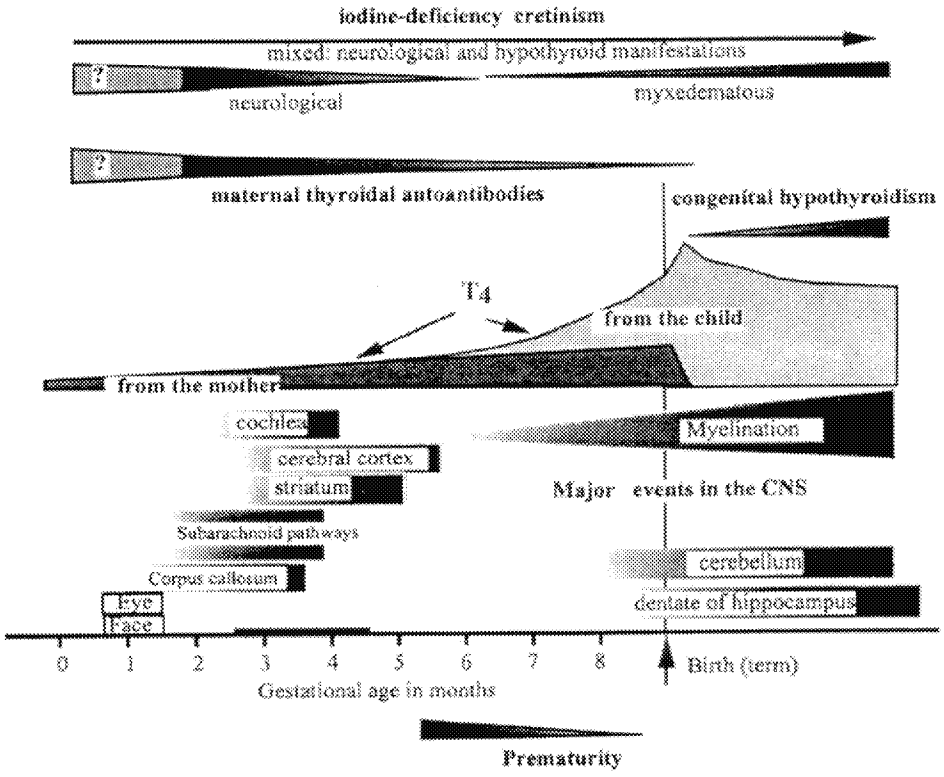


Too much or too little thyroid hormone can lead to illness. Thyrotoxicosis occurs when tissues are exposed to excess amounts of thyroid hormones, resulting in specific metabolic changes and pathophysiologic alterations in organ function. The most frequent cause of thyrotoxicosis is Graves' disease, accounting for 60 to 90 percent of cases (Dillmann, 2000). Graves' disease is an autoimmune disorder with B-lymphocytes producing immunoglobulins, some of which bind to and activate the TSH receptor, stimulating excess thyroid growth and hormone secretion. Hypothyroidism results from decreased secretion of thyroid hormone from the thyroid gland; it can be caused by destruction of thyroid tissues or defects of thyroid hormone production (e.g., congenital enzyme defects, congenital mutations in TSH receptor, iodine deficiency or excess). In some rare occasions, hypothyroidism can also be caused by pituitary or hypothalamic diseases.

The most severe neurological impairment resulting from decreased thyroid hormone production or iodine deficiency is cretinism. Characteristics of cretinism include mental retardation, spastic dysplasia, and problems with gross and fine motor control. In some extreme forms, the affected individuals cannot walk or stand. A number of studies indicate that even less severe iodine deficiency can reduce maternal serum thyroid hormone levels and may subsequently impair the brain development of the offspring (Glorieux *et al.*, 1988; Rovet *et al.*, 1987; Tillotson *et al.*, 1994; Vermiglio *et al.*, 1990; Pop *et al.*, 1999, 2003; Haddow *et al.*, 1999; Bleichrodt and Born, 1994). These studies are reviewed in further detail in the following sections. The nature and severity of the adverse effects are related to the degree of iodine deficiency or the extent of maternal thyroid hormone decrease.

Most data suggest that fetal damage during development is inversely related to maternal serum T4 levels (Pop *et al.*, 2003; Kooistra *et al.*, 2006). Maternal serum free T4 (fT4) is able to pass through the placenta and is converted to T3 in the fetal brain. The T3 generated in the fetal brain is believed to be necessary for the development of the brain, specifically the cerebral cortex, the extrapyramidal system, and the cochlea (Porterfield, 2000). The availability of a minimum level of maternal fT4 is crucial for proper fetal brain development in the first and second trimesters, as the fetal thyroid is not fully mature and functional during that time period. Figure 2 shows the approximate timing of major insults to the brain resulting from hypothyroxinemia (a low level of serum T4), superimposed on major neurodevelopmental events (Morreale de Escobar *et al.*, 2000).

Figure 2. Approximate Timing of Major Insults to the Brain Resulting from Hypothyroxinemia, Superimposed on Major Neurodevelopmental Events.



Thyroid Problems in Pregnant Women with Low Iodine Intake

A number of human studies have shown that pregnancy stresses the thyroid (Crooks *et al.*, 1967; Glinoer *et al.*, 1990, 1992, 1995; Smyth *et al.*, 1997; Caron *et al.*, 1997; Brent, 1999; Kung *et al.*, 2000). In areas of iodine deficiency (e.g., intake level <100 µg/day), there is an increased risk of abnormally low serum T3 and T4 levels, and thyroid enlargement and goiter in pregnant women. The nature and severity of changes in thyroid function are related to the severity of

the iodine deficiency. In an epidemiologic survey reported by Delange and Ermans (1991; as cited in Delange, 1994), the investigators found the prevalence of goiter in an area with severe iodine deficiency is influenced by age and sex, with maximal frequency in females during puberty and childbearing age (Figure 3).

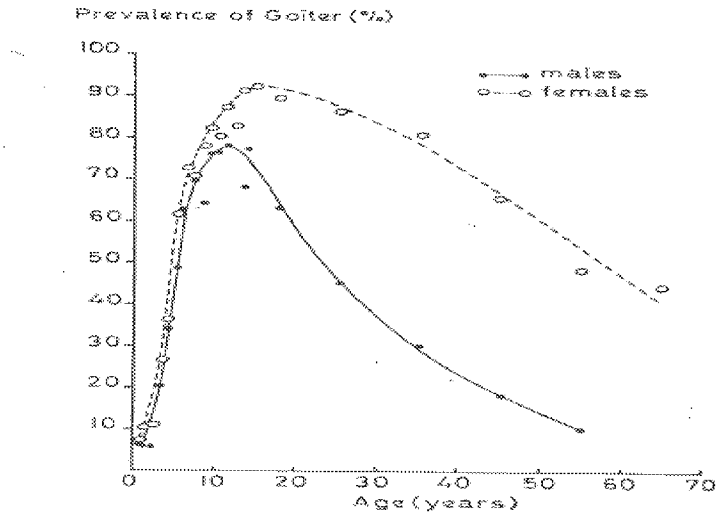


Figure 3. Changes in the Prevalence of Goiter as a Function of Age and Sex in Severe Endemic Goiter (Idjwi Island, Zaire) (Delange, 1994)

Crooks *et al.*, 1967. Crooks *et al.* (1967) studied enlargement of the thyroid gland in pregnant and non-pregnant women in Aberdeen, Scotland and Reykjavik, Iceland. In the Scotland study, they found that the thyroid gland was visible and palpable in 70 percent of pregnant women but in only 37 percent of non-pregnant women in the reproductive age group. By contrast, in the Iceland study, the frequency of thyroid enlargement was about the same in pregnant (23 percent) and non-pregnant women (19 percent). The authors (1967) suggested that the results can be explained by the fact that Icelandic diet is based on fish and contains high levels of iodine. This hypothesis is supported by the significantly higher mean plasma inorganic iodine concentration measured in non-pregnant Icelandic women (0.691 µg/dL) compared to the mean of 0.420 µg/dL found in Scottish non-pregnant women ($p<0.001$).

Glinoer *et al.*, 1990. Glinoer *et al.* (1990) suggested that in conditions of marginally low iodine intake, pregnancy constituted a goitrogenic stimulus. They followed a group of 606 healthy pregnant women in Brussels, Belgium, an area of marginally low iodine intake (50-70 µg/day), and monitored their T3, T4, TSH, and human chorionic gonadotropin (hCG) levels in serum during the first, second, and third trimesters. All subjects were evaluated clinically and determined to be without detectable thyroid abnormality at the beginning of the study. The authors found that a normal thyroid is faced with a triple challenge during pregnancy. First, there is a significant increase in circulating levels of the major T4 transport protein, thyroglobulin (Tg), in response to high estrogen

levels. As a result, the thyroid has to increase its T4 output in order to maintain a stable T4/thyroglobulin ratio of 37-40 percent.

Second, several thyroidal stimulating factors of placental origin (mainly hCG) are produced in excess. This contributes to a decrease of serum TSH (mainly in the first half of gestation) and an increase in thyroid volume (Table 6). They found that during pregnancy thyroid volume increased by an average of 18 percent. This increase was statistically significant and thyroid size increased in a majority of women (73 percent). Goiter, defined as thyroid volume greater than 23 mL, was found in nine percent of the cohort at delivery.

Table 6. Changes in Mean Thyroid Volume in Healthy Women during Pregnancy (from Glinoer *et al.*, 1990)

Stage of Pregnancy	N	Total volume (mL)
First trimester	168	12.1 ± 4.5
Second trimester	172	12.8 ± 4.5
Third trimester	33	13.9 ± 4.8[a]
Delivery	179	15.0 ± 6.8[b]

[a] $p < 0.03$ vs. beginning of pregnancy.
[b] $p < 0.001$ vs. beginning of pregnancy.

Third, pregnancy is accompanied by a decrease in the availability of iodide for the maternal thyroid, due to increased renal clearance (Aboul-Khair *et al.*, 1964; as cited in Glinoer *et al.*, 1990) and losses to the feto-placental complex during late gestation, resulting in a relative iodide deficiency state.

Glinoer *et al.*, 1992. In a related study, Glinoer *et al.* (1992) monitored the thyroid condition of pregnant women in an area without overt iodine deficiency, but with a marginal iodine supply (less than 100 µg/day in 80 percent of women). They found that maternal thyroid function at delivery was characterized by a relative hypothyroxinemia; increased T3/T4 ratios, indicating preferential T3 secretion; slightly increased TSH levels within the normal range in 97 percent of women; increased serum thyroglobulin values, which were above normal in 60 percent of women; and goiter formation in almost 10 percent of women. In the newborns, they found fT4 levels were significantly higher than in the respective mothers. However, mean neonatal TSH and Tg levels were significantly higher than maternal values. Furthermore, these values were highly correlated with maternal data, suggesting the limited availability of iodine was the common link.

In a review paper, Glinoer (2001) again stressed the profound alterations in the thyroid economy associated with pregnancy. In healthy iodine-sufficient pregnant women, this leads to a physiological adaptation of the thyroid and an increased production of thyroid hormones. When gestation takes place in conditions with iodine restriction or deficiency, pregnancy may lead to pathological alterations affecting both thyroid function and the anatomical

integrity of the thyroid gland. The more severe the iodine deficiency, the more obvious, frequent, and profound the potential maternal and fetal repercussions.

Smyth *et al.*, 1997. Supportive results were reported in two other studies, one in Ireland and the other in France. Smyth *et al.* (1997) evaluated ultrasound-measured thyroid volume of 115 pregnant women during one of the three trimesters. These women (Group A) were enrolled based on availability, and each trimester's study group comprised different individuals. Control values for thyroid volume were obtained from 95 pre-menopausal females. All subjects were from Dublin, Ireland, an area of moderately low dietary iodine intake (median urinary iodine was 82 µg/day). All pregnant women studied delivered live-born, normally formed, singleton infants and received no iodine-containing supplements during their pregnancy. The authors reported that the mean thyroid volume of 13.9 ± 0.8 mL, observed in the first trimester, was significantly greater than the control value (11.3 ± 0.5 mL; $p < 0.05$) and reached a maximum of 16.0 ± 0.7 mL, a 47 percent increase ($p<0.01$), in the third trimester.

In a related study, Smyth *et al.* (1997) studied a group of 38 pregnant women (Group B), prospectively. Casual urine samples were collected sequentially during the 3 trimesters of pregnancy and at approximately 6 weeks postpartum. Of those 38 subjects, 20 had thyroid ultrasound scans during each trimester of pregnancy and at 6 weeks postpartum. Thyroid volumes greater than 18.0 mL were defined as enlarged. The number of enlarged thyroids increased from the non-pregnant control value of 6.3 percent, through 19.5 percent in the first trimester, to reach a plateau of approximately 32 percent in the second and the third trimesters, which was maintained up to 40 days postpartum.

Urinary iodine of the women in Group A and Group B were also measured. Urinary iodine measurements collected from 1,063 pre-menopausal women over a one-year period were used for comparison. The researchers found that urinary iodine levels measured throughout the pregnancies of the women in Group A and Group B (Table 7) were higher than in the controls (median 70 µg/L). They suggested that in an area of moderately low dietary iodine intake, urinary iodine loss during pregnancy may result in maternal thyroid enlargement.

Table 7. Median Urinary Iodine Excretion (µg/L) in Pregnancy (Smyth *et al.*, 1997)[a]

	First Trimester	Second Trimester	Third trimester
Group A	135	122	122
Group B	155	122	115

[a]Some of the values were estimated from a graph.

Caron *et al.*, 1997. In a prospective study, Caron *et al.* (1997) evaluated the thyroid condition of 347 pregnant women living in the southwest of France (with an estimated urinary iodine excretion value of 50 µg/day). Iodine concentration in urine samples and serum thyroid hormone measurements were taken at initial

presentation (before 12 weeks of gestation), and during the nine months of pregnancy. Mean urinary iodine levels were low during the first trimester (6.9 ± 0.4 µg/dL), as well as during the ninth month of pregnancy (8.6 ± 0.6 µg/dL). A thyroid ultrasound was performed one to five days after delivery in 246 mothers. During pregnancy fT4 and T3 concentrations decreased ($p<0.001$), and TSH and Tg concentrations increased ($p<0.001$). Thyroid hypertrophy (thyroid volume greater than 18 mL) was present in 29 percent of the mothers. The percentage of thyroid hypertrophy at delivery was associated with urinary iodine concentration during the first trimester of gestation: 15.4 percent (urinary iodine < 5 µg/dL), 9.2 percent (urinary iodine 5-10 µg/dL), and 3.5 percent (urinary iodine > 10 µg/dL) (Figure 4). Goiter (thyroid volume greater than 22 mL) was present in 11 percent of the mothers. The researchers concluded that in areas with a marginally low iodine supply, pregnancy constitutes a goitrogenic stimulus.

Kung *et al.*, 2000. In another prospective study, Kung *et al.* (2000) studied 230 pregnant women living in a borderline iodine sufficient area (Hong Kong). The median urine iodine concentration in healthy adults was 0.77 µmol/L (9.8 µg/dL) in Hong Kong, which was close to the World Health Organization cut-off value of 0.79 µmol/L (or 10 µg/dL) for iodine sufficiency. When recruited into the study, all pregnant women were in their first trimester; subjects with a history of thyroid dysfunction were excluded. These women were prospectively studied at approximately 12-14 weeks, 20-24 weeks, and 36 weeks of gestation, as well as 6 weeks and 3 months postpartum for thyroid function, thyroid volume by ultrasound examination, and urine iodine concentration. Study results are presented in Table 8. The investigators showed that in an area of borderline low dietary iodine intake, pregnancy was an important stress to the maternal thyroid axis. Pregnancy caused an average 30 percent increase (range, 3 – 230 percent) in thyroid volume, with some subjects having a more than two-fold increase. This thyroid enlargement persisted and failed to revert completely even 3 months after delivery.

The researchers also reported that 14 women with excessive thyroidal stimulation in the second trimester had lower urine iodine concentrations and larger thyroid volumes throughout pregnancy. Furthermore, their neonates had higher cord TSH, Tg, and slightly higher thyroid volumes than the neonates of 216 pregnant women without evidence of thyroid stimulation. Seven neonates (50 percent) born to these women had subnormal fT4 levels at birth.

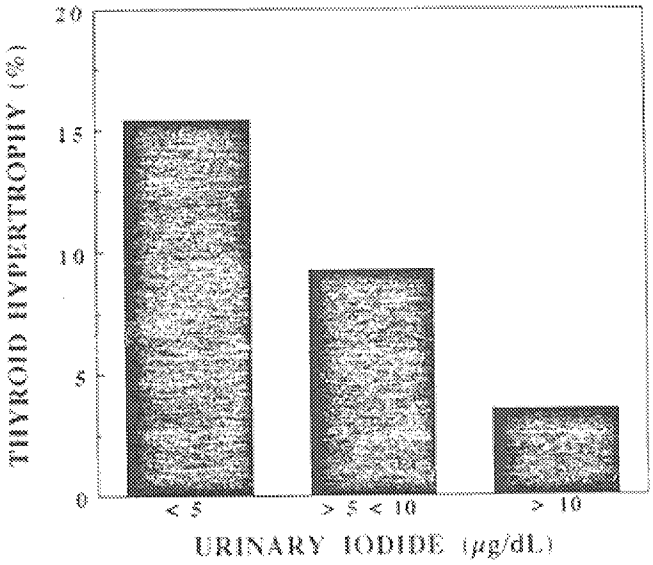

Figure 4. Percentage of Maternal Thyroid Hypertrophy in Relation to Urinary Iodine Concentration during the First Trimester of Pregnancy (Caron *et al.*, 1997)

Table 8. Change of Thyroid Function Tests, Thyroidal Volume, and Urinary Iodine Level of Women during and after Pregnancy (Kung *et al.*, 2000)

	First trimester	Second trimester	Third trimester	Postpartum 6 weeks	Postpartum 3 months
Total T4 (nmol/L)	154 (132-176)	126 (110-143)[a]	125 (106-142)[a]	89 (81-98)[b]	92 (82-101)[b]
Free T3 (pmol/L)	3.9 (3.6-4.3)	3.4 (3.1-3.7)[a]	3.3 (3.0-3.7)[a]	4.0 (3.7-4.4)	4.3 (4.1-4.6)

[b] $p < 0.01$ vs. first trimester

Another source of data supporting the concept that normal pregnancy requires increased thyroid hormone production comes from the observation that women previously diagnosed with hypothyroidism on adequate T4 replacement doses often require an increase in their T4 doses during pregnancy (Table 9).

Table 9. Thyroid Hormone Requirement in Pregnancy (Brent, 1999)

Study	Mean daily dose (µg)	Fraction of women requiring an increased dose	Mean dose increase for those who had an adjustment (µg)
Pekonen *et al.* (1984)	141	7/34 (21%)	62
Mandel *et al.* (1990)	148	9/12 (75%)	46
Tamaki *et al.* (1990)	-	4/4 (100%)	-
Girling and de Swiet (1992)	142	9/32 (28%)	68
Kaplan (1992)	154	27/42 (64%)	42
Pooled data	146	56/124 (45%)	46

Romano *et al.*, 1991; Pedersen *et al.*, 1993; Glinoer *et al.*, 1995. These are three prospective studies showing that in an area with marginal or moderate iodine deficiency, iodine supplementation often can reduce the stress on the thyroid during pregnancy. The first study was carried out in L'Aquila, Italy, an area with moderate iodine deficiency (Romano *et al.*, 1991). There were 35 pregnant women in the study, all of whom had a normal pregnancy and no history of thyroid disease. They had a mean age of 27.1 years (±3.8) and a mean body weight of 61.6 kg (± 4.9) at the first examination during the first trimester. Pregnant women were randomly assigned into group A (n=17) or group B (n=18). Immediately after the first examination, iodide salt equivalent to a daily intake of about 120 to 180 µg iodide was prescribed to all the women in group A. Each trimester all pregnant women in both groups were subjected to three ultrasonographic evaluations of thyroid volume and to measurement of body weight. During each examination, 24-hour urine samples were also taken to determine the iodine urinary excretion. Romano *et al.* (1991) reported that TSH levels of all the subjects were within the normal range and TSH levels measured in group A did not statistically differ from those measured in group B. The effect of iodine supplementation was confirmed by urinary iodine measurements. A significant increase in urinary iodine excretion was found at the second and third examination ($p<0.0001$ and $p<0.01$, respectively, Table 10) only in group A, treated with iodide salt.

Table 10. Iodine Excretion (µg/24 hours) in Both Groups at Each Trimester (mean± standard deviation) (from Romano *et al.*, 1991)

	First trimester	Second trimester	Third trimester
Group A	37.0±36.0	154.0±59.0[a]	100.0±39.0[b]
Group B	30.5±42.0	55.0±35.0	50.0±37.0

[a]$p<0.0001$
[b]$p<0.01$ vs. first trimester

Thyroid volume did not change throughout pregnancy in the group treated with iodide salt. However, in the control group (Group B) there was a statistically significant increase in thyroid volume from the first to the third trimester (mean increase = 1.6 ± 0.6 mL; $p<0.0001$). Romano *et al.* (1991) concluded that an adequate dietary iodine intake is necessary to prevent the development of gestational goiter, and iodine deficiency is the main causative factor of thyroid enlargement during pregnancy.

A similar study was also carried out in East Jutland, Denmark, an area with a median daily urinary iodine excretion around 50 µg (Pedersen *et al.*, 1993). The researchers selected 54 normal pregnant women and randomly divided them into iodine-treated (28 subjects) and untreated groups (26 subjects). Before iodine supplementation was initiated, the measured variables were nearly identical in the two groups. Treated subjects received 200 µg iodine/day starting from weeks 17-18 of pregnancy until 12 months after delivery. All women were followed at regular intervals during pregnancy. In the control group, serum TSH, serum Tg, and thyroid size showed significant increases during pregnancy. These variations were less in the iodine supplementation group (Figures 5, 6, and 7).

Iodine did not induce significant variations in serum T4, T3 or free T4 in this study. Pedersen *et al.* (1993) concluded that a relatively low iodine intake during pregnancy leads to thyroid stress, with increases in Tg release and thyroid size. It is important to note that even in the iodine-supplement group, there was a significant increase in thyroid volume during pregnancy. Notably, the size of the thyroid returned to initial values one year after delivery independent of iodine supplementation. Pedersen *et al.* (1993) were concerned that thyroidal stress during pregnancy in an area of iodine deficiency can lead to goiter, which is primarily reversible, as was shown in the study. However, at some point iodine deficiency triggers, by an unknown mechanism, irreversible changes in the thyroid with autonomous growth and function and may lead to high incidence of multinodular toxic goiter in elderly subjects. It was suggested that iodine deficiency during pregnancy or even during fetal life could be an important factor for the late development of thyroid autonomy.

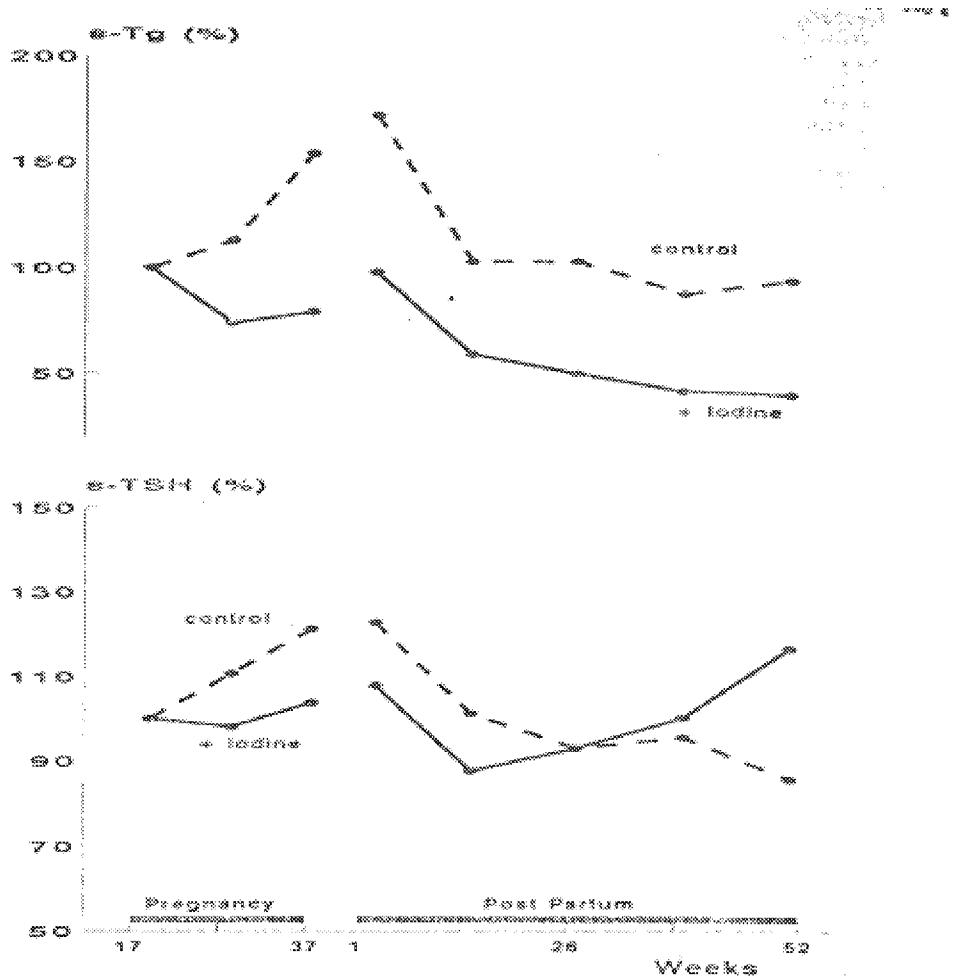

Figure 5. Serum Tg and TSH during Pregnancy and for 52 Weeks Postpartum in Women Receiving Iodine Supplementation and Control Women, as a Percentage of the Initial Values (from Pedersen *et al.*, 1993). Median values are shown. The increase in serum Tg during pregnancy in the control group was statistically significant ($p<0.01$), but the first value obtained during pregnancy and the values obtained one year after delivery were not different. Tg values from the two groups were significantly different at all periods, except before initiation of iodine supplementation. The increase in serum TSH in the control group during pregnancy was statistically significant ($p<0.01$), whereas no differences between values were found in the iodine supplemented group ($p=0.29$, by Friedman's test). During the postpartum period, no significant TSH differences between the groups were found.

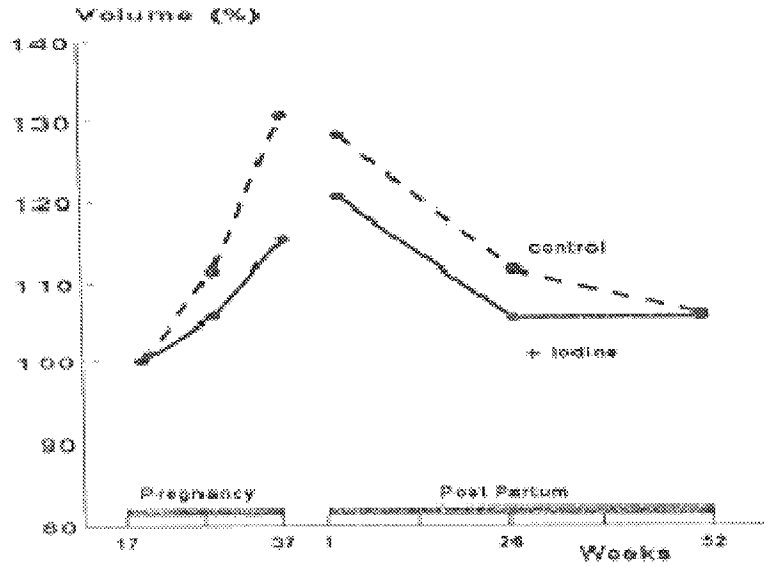

Figure 6. Median Thyroid Volume during Pregnancy and 52 Weeks Postpartum in Women Receiving Iodine Supplementation and Control Women, as Percent of Initial Values (from Pedersen *et al.*, 1993). In both groups, statistically significant increases during pregnancy and decreases during the postpartum period were found ($p<0.05$). The increase during pregnancy in controls was higher than that in the iodine supplemented group ($p<0.05$).

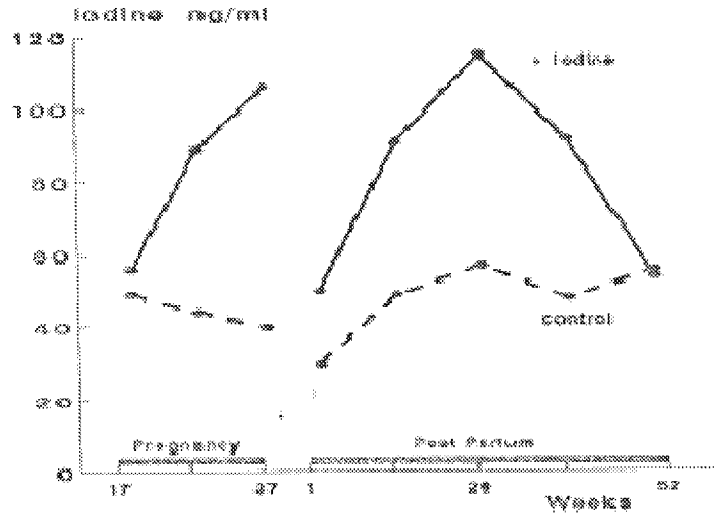

Figure 7. Iodine Concentration in Spot Urine Samples during Pregnancy and for 52 Weeks Postpartum in Women Receiving Iodine Supplementation and Control Women (Pedersen *et al.*, 1993). The last sample was obtained after iodine supplementation was stopped.

Glinoer *et al.* (1995) studied a group of euthyroid pregnant women with mild to moderate iodine deficiency and found pregnancy-related stresses on the thyroid could be prevented by the administration of potassium iodine or potassium iodine plus thyroxine (L-T4). They selected 180 pregnant women at the end of the first trimester on the basis of biochemical criteria of excessive thyroid stimulation, defined as serum thyroglobin > 20 µg/L associated with a low normal fT4 index (<1.23) and/or an increased T3/T4 ratio (>$25x10^{-3}$). The subjects were randomized in a double-blind protocol into three groups and treated until term with either placebo (Group A), potassium iodine (100 µg/day) (Group B), or potassium iodine (100 µg/day) plus L-T4 (100 µg/day) (Group C). At the beginning of the study, all the subjects were mildly or moderately iodine deficient as indicated by a median urinary iodine concentration of 36 µg/L. Only 10 percent of women had urinary iodine above 80 µg/L. After therapy was instituted, the urinary iodine concentrations in Groups B and C rose to approximately 75-130 µg/L in the second and third trimesters; while urinary iodine of Group A remained low during gestation and at delivery.

Study results showed that total T4 levels of all groups increased during the second and third trimesters compared to those measured during the first trimester. However, the increases observed in Group A (4 percent and 7 percent for the second and third trimesters, respectively) were much smaller than those observed in Group B (9 percent and 11 percent) and Group C (19 percent and 15 percent). Glinoer *et al.* (1995) also reported that in Groups A and B, the ratios of T3/T4 were higher than normal at the start of the therapy and remained elevated during gestation. However, in Group C the ratios decreased rapidly toward normal and were maintained at a level of approximately 22 x 10^{-3}. These results indicated that thyroid stimulation associated with pregnancy and leading to preferential T3 secretion by the thyroid was suppressed after potassium iodide plus L-T4 administration. Glinoer *et al.* (1995) found an average increase of 30 percent in thyroid volume in Group A. Sixteen percent of the women in this group developed a goiter during gestation, with thyroid volumes up to 34 mL at delivery. The increment in thyroid volume was much less in Group B (mean increase of 15 percent) and in Group C (mean increase of 8 percent). Furthermore, goiter formation in Groups B (10 percent) and C (3 percent) was less frequent than that in Group A. In the same study, Glinoer *et al.* (1995) also evaluated the thyroid status of the newborns, 3-6 days after delivery. They found that the mean thyroid volume of newborns in Group A (1.05 ± 0.05 mL) was significantly larger than those in Groups B (0.76 ± 0.05 mL) and Group C (0.75 ± 0.05 mL). Furthermore, glandular hyperplasia (thyroid volume >1.4 mL) was found in 10 percent of newborns in Group A (range 1.5-2.2 mL) compared to none in Groups B and C ($p=0.01$, by χ^2 test). Glinoer *et al.* (1995) found the study results in agreement with other investigations on goitrogenesis during pregnancy in areas with less than adequate iodine supply.

Rotondi *et al.*, 2000. This study found an association between thyroid size and the number of their previous pregnancies in an area with moderate iodine deficiency. The researchers studied the size of thyroids of 208 non-goitrous

healthy females by ultrasound examination. All subjects lived in a region (Naples, Italy) that is known to have moderate iodine deficiency, with usual urinary levels ranging from 40-100 µg/day. All subjects had serum free T3, fT4, and TSH measurements, as well as thyroglobulin antibody and thyroid peroxidase antibody detection. All subjects were clinically and biochemically euthyroid and had no detectable thyroid autoantibodies. The subjects were divided into five groups, according to the number of completed pregnancies (0, 1, 2, 3, 4 or more term pregnancies). The researchers found mean thyroid volume increased progressively among the groups; group 0 (14.8±0.7 mL); group I (16.0±0.9 mL); group II (17.1±0.6 mL); group III (18.2±0.6 mL); group IV (20.3±0.9 mL). The difference in the increases in thyroid volume was statistically significant between group 0 and groups III ($p<0.01$) and IV ($p<0.001$), and also between group I and group IV ($p<0.05$). No independent effect of body weight and age on thyroid volume was seen. Based on the results, Rotondi *et al.* (2000) suggested that, in an area with moderate iodine deficiency, there is a cumulative goitrogenic effect of successive pregnancies and the goitrogenic effect of pregnancy is not fully reversible.

As shown above, several studies have identified associations between pregnancy and increased thyroid size. However, as we review in the following paragraphs, this effect has not been seen in all studies.

Gerghout *et al.*, 1994. These researchers studied 10 healthy women before and during a normal pregnancy in an iodine replete area of Amsterdam, the Netherlands. They found no change in thyroid volume during pregnancy (data given before pregnancy and during first, second, and third trimesters, respectively: 10.3 ± 5.1, 10.6 ± 4.4, 9.6 ± 3.8, and 9.4 ± 3.0 mL. Urinary iodine levels or dietary iodine intakes were not reported.

Long *et al.*, 1985. These researchers studied a group of pregnant teenagers and found the frequency of goiter in this group was not higher than that in non-pregnant teenagers. They studied 309 consecutive pregnant adolescent girls who were admitted to a medical center in San Diego, California from August 1978 through December 1982. A group of 600 adolescent girls was used as controls to establish the prevalence of goiter in non-pregnant adolescents. The mean gestational age for the first visit was 22 weeks. A thyroid gland was defined as enlarged if it was visible and/or palpable and had a transverse span of $\geq$ 6 cm. Eighteen goiters (6 percent) were identified in the pregnant teenagers versus 27 goiters (5 percent) in the control group. It should be noted that the detection method used in the study is not as sensitive and reliable as the ultrasound detection used in the more recent studies. Long *et al.* (1985) concluded that abnormalities of size and function of the thyroid gland were not more prevalent during the stress of reproduction at a young age.

Levy *et al.*, 1980. This study examined the thyroid glands of 49 matched pairs of women in Ohio, one pregnant and one non-pregnant woman per pair. All pregnant women were at least 20 weeks into the pregnancy and had no personal

history of thyroid abnormality. The subjects were paired by race and age (within 5 years) and examined by multiple observers. Observers independently graded each thyroid as "not palpable," "palpable but not enlarged," or "enlarged." They also compared the size of the two glands relative to one another for every pair of subjects. Levy *et al.* (1980) found that in 22 pairs the pregnant woman had the larger thyroid, whereas in 20 pairs the opposite was true. In six pairs the thyroid glands were not palpable, and in one pair the thyroid glands were of equal size. Five pregnant and three nonpregnant women had clinically significant goiters. None of the differences was statistically significant. These results are consistent with the study of Crooks *et al.* (1967) conducted in Reykjavik, Iceland, which showed that pregnancy did not impact the thyroid gland when iodine intake was adequate.

Liberman *et al.*, 1998. This investigation studied the serum T4, TSH, and serum and urinary inorganic iodine levels during the first, second, and third trimesters and after delivery of 16 women. They reported significantly higher levels of mean serum T4 during the pregnancy than after delivery. Similar levels of serum TSH, serum inorganic iodine, and urinary iodine were measured during pregnancy and after delivery. The daily iodine intakes of the subjects were high, as indicated by the relatively high average urinary iodine levels (459 – 786 µg/day). Liberman *et al.* suggested that pregnancy does not have an important influence on serum inorganic iodine or thyroid status in iodine-sufficient regions.

Adverse Neurological Development with In Utero Iodine Deficiency or Low Thyroid Hormone Levels

The changes in thyroid function associated with pregnancy are related to increased hormone requirements. The need can only be met by a proportional increase in hormone production and is dependent upon the availability of iodine in the diet (Glinoer, 2001). The National Academy of Sciences has recommended an Estimated Average Requirement of 160 µg/day and a Recommended Dietary Allowance of 220 µg/day for pregnant women (NAS, 2001). These values are higher than the Estimated Average Requirement of 95 µg/day and the Recommended Dietary Allowance of 150 µg/day for non-pregnant adults (age 19 years and older).

Iodine deficiency disorders range from endemic cretinism to endemic goiter and less severe forms of brain abnormalities. The impact of iodine deficiency differs depending on the age and life stage of the affected individual, as well as the degree of iodine deficiency. The most severe problems caused by iodine deficiency are among fetuses, neonates, and infants because of the irreversible changes that can occur during this period of rapid structural and behavioral development. Cognitive impairment is the most common finding seen with iodine deficiency, and thyroid disorders during pregnancy have been shown to increase the risk of neurologic damage in offspring (Hetzel and Maberly, 1986; as cited in Hollowell and Hannon, 1997). It was considered a paradox that in areas of iodine deficiency, children with cretinism, but with functioning thyroid glands, had

more severe central nervous system damage than some children who were missing a thyroid gland. For prevention of central nervous system damage, iodide has to be supplied before conception or early in the first trimester, a time in development before the fetal thyroid is known to be functional (Hollowell and Hannon, 1997). The finding that maternal T4 reaches the fetus (Vulsma *et al.*, 1989) made it understandable that maternal thyroid hormones are necessary for brain development during early fetal development, and severe central nervous system damage can occur as a result of maternal thyroid deficiency.

This theory is supported by the results of a number of animal and human studies.

Animal Studies in Neonates Born to Dams with Iodine Deficiency or Low Thyroid Hormone Levels

Obregon *et al.*, 1984 and Woods *et al.* , 1984 and others. Obregon *et al.* (1984) and Woods *et al.* (1984) showed that fetal rat tissues, including brain, contained T4 and T3 before fetal thyroid hormone was produced. Several researchers also reported that nuclear T3 receptors in brain tissues obtained from rat and human fetuses early in gestation (before the development of the fetal thyroid) were relatively saturated with T3 (Bernal and Pekonen, 1984; Perez Castillo *et al.*, 1985; Ferreiro *et al.*, 1988; as cited in Burrow *et al.*, 1994). The presence of occupied T3 nuclear receptors in brain tissues early in fetal development supports a role for maternal thyroid hormones in the maturation of the brain.

Argus Research Laboratories, 1998a and 2001. In two animal developmental studies (discussed in an earlier section), ammonium perchlorate was administered to female Sprague-Dawley rats via drinking water at target doses between 0.01 and 30 mg/kg-day. Morphometric analysis of the pups revealed significant changes in sizes of a number of brain regions (e.g., corpus callosum), although a simple dose-response relationship was not observed for any of the changes (Figure 11).

Potter *et al.*, 1982 and Hetzel *et al.*, 1987. Severe iodine deficiency has been shown to cause abnormal fetal brain development in a number of animal species. Potter *et al.* (1982) reported that severe iodine deficiency in sheep caused reduction in fetal brain weights and in brain DNA and protein from 70 days of gestation to parturition. They also found unusual morphological changes in both the cerebral hemispheres and the cerebellum of the fetal brains. Hetzel *et al.* (1987) reported that severe iodine deficiency caused abnormal fetal brain development in rat, marmoset, and sheep. The abnormalities included reduced brain weight, change in cell density in the cerebral hemispheres, reduced synaptic counts in the visual cortex, and reductions of brain DNA and brain protein.

Lavado-Autric *et al.*, 2003. In this study, the investigators evaluated the effects of a low iodine diet (LID) with (LID-2) or without (LID-1) 1 percent potassium perchlorate in pregnant rats. The potassium perchlorate was used to produce hypothyroxinemia in the pregnant rats. Cell migration and cytoarchitecture in the somatosensory cortex and hippocampus of the 40-day-old offspring were examined (n = 5-7 pups per group). The number of dams per group was not provided. According to the authors, the reproductive performance of the LID-2 animals and the post-natal growth of their pups were normal (although no details are provided). Serum T4 levels were 90 percent lower in both the LID-1 and LID-2 dams than in controls. Levels of serum T3 (the hormonally active form of thyroid hormone) in the LID-1 and control dams were similar. The mean T3 in the LID-2 dams was lower than controls, although the difference was much less than that seen for T4 (mean serum T3 (in ng/mL) in controls: 0.73 ± 0.02 (standard error); in LID-1 animals: 0.65 ± 0.15; in LID-2 animals: 0.37 ± 0.06). Litter size, body weight or postnatal growth measures were not affected.

Using BrdU labeling of cells at specific time points of development, the authors took advantage of the normal migration patterns of cortical neuronal cells to investigate the impacts of thyroid deficiencies on normal structural brain development. Normally, cells born later migrate past cells born earlier and occupy more superficial layers of the cortex. When BrdU was administered on gestation days 14-16, there was a decrease in the proportion of BrdU-labeled cells in the deeper cortical layers and an increase in the subcortical white matter in the LID-1 and -2 offspring compared to controls. The researchers noted that gestation days 14-16 are before the fetal thyroid begins producing thyroid hormone (which usually starts around day 17.5-18). As such, these effects are likely due to deficiencies in maternal thyroid hormones rather than any deficiency of the fetal thyroid. When BrdU was administered on gestation days 17-19, there was a decrease in labeled cells in the superficial layers and an increase in the deeper layers of the cortex. The researchers used single- and double-label immunostaining to find that the BrdU-labeled cells were neurons, not glia.

Overall, these findings provide evidence that the normal pattern of neuronal cell migration in the cortex during fetal development can be disrupted by maternal hypothyroxinemia. In addition, since these effects were assessed in the offspring at postnatal day 40, these findings likely represent permanent rather than temporary alterations to the cortical cytoarchitecture (Zoeller, 2003). This study was different from earlier studies because the level of maternal hypothyroidism introduced was relatively mild and treated pups or dams could not be distinguished from controls by their weight, growth, reproductive performance, or physical appearance. In previous studies, severe hypothyroidism was introduced in the dams of pups by surgical thyroidectomy or strong goitrogens such as high dose methimazole.

The results of this study could potentially provide some mechanistic explanation for the findings in human studies which have linked decreases in maternal thyroid hormone during pregnancy to subsequent altered neurological development in

the offspring (e.g., Pop *et al*., 1999, 2003; Haddow *et al*. 1999). Migration defects in the brain have been associated with neurological deficits in humans (Sun *et al*., 2002). However, it is not currently known how the particular effects seen in this study might impact long-term neurological function.

Auso *et al*., 2004. Normal rat dams were given the goitrogens 2-mercapto-1-methylimidazole on gestation days 12 through 15. Maternal thyroid hormone levels decreased transiently by about 30 percent compared to normal values. There were no clinical signs of hypothyroidism. Mean T4 (± SEM) in the treated and control dams was 11.60 ± 0.67 and 15.90 ± 1.89, respectively. BrdU was injected from gestation days 14-16 or 17-19 and pups were tested for audiogenic seizure susceptibility 39 days after birth. The cytoarchitecture and radial distribution of the BrdU-labeled neurons on postnatal day 40 were affected in 83 percent of the pups from the treated dams. Infusion of T4 at gestation days 13-15, but not during days 15-18 avoided these alterations. An increase in seizures and wild runs in response to acoustic stimulus was seen in the pups from treated dams versus controls. These data provide evidence that transient and relatively mild decreases in maternal T4 during early pregnancy can lead to permanent architectural changes in the brain.

van Wijk *et al*., 2008. This report describes how a lack of thyroid hormone during early development can result in multiple morphological and functional alterations in the developing brain of Wistar (HsdCpb:WU) rats. The behavioral effects of perinatal and chronic hypothyroidism during development in offspring (male and female) of hypothyroid rats were assessed. Twelve dams (starting 2 weeks prior to mating) and offspring (one litter per dam, eight pups per litter) were fed an iodine-poor diet and drinking water with 0.75 percent sodium perchlorate. This continued either until weaning (perinatal hypothyroidism) or until the day of killing (chronic hypothyroidism). The pups were tested for neuromotor competence, locomotor activity and cognitive function until postnatal day 71, comparing them to age-matched control rats. Early neuromotor competence, as assessed in the grip test and balance beam test, was impaired in both chronic and perinatal hypothyroidism groups. The open field test, assessing locomotor activity, revealed hyperactive locomotor behavioral patterns only in the chronic hypothyroid animals. The Morris water maze test assessed cognitive performance and showed that chronic hypothyroidism affected spatial memory in a negative manner, with perinatal hypothyroidism impairing spatial memory in female rats only. Overall, the effects of chronic hypothyroidism appeared to be more pronounced than the effects of perinatal hypothyroidism. This suggests that the early effects of hypothyroidism on functional alterations of the developing brain depend on the timing of the thyroid hormone deficiency during development and the impacts may be decreased, but not eliminated, if the deficiency is improved.

Gilbert and Sui, 2008. These investigators exposed 106 pregnant Long-Evans rats to 0, 30, 300, or 1,000 ppm perchlorate in drinking water (equivalent to 0, 4.5, 44.2, or 140.3 mg/kg-day) from gestation day 6 until weaning (postnatal day

30). Adult male offspring from an unstated number of litters/group were studied with a series of behavioral tasks. These included motor activity as a general test of neurotoxicity (8-11/group), the Morris maze as a spatial learning test (11-17/group), and fear conditioning as a reflection of the integrity of the hippocampus (number of animals unstated). The authors also utilized neurophysiologic measures of synaptic function in the hippocampus including long-term potentiation (LTP), a well-established model of synaptic plasticity (14-17/group). There was no positive control. In the dams, T4 was reduced relative to controls by 16 percent, 28 percent, and 60 percent in the 30, 300, and 1,000 ppm dose groups, respectively. Little change was seen in T3 across dose groups and TSH levels were only increased in the highest dose group (1,000 ppm). Perchlorate dose was not associated with body weight in the dams or pups, or with pup eye opening, brain or hippocampal weights.

In the pups, small decreases (i.e., 10-20 percent) in serum T3 and T4 were seen in the two higher dose groups compared to controls on postnatal day 21. However, all serum hormone levels returned to control levels in adulthood. Perchlorate exposure did not affect motor activity, spatial learning, or fear conditioning in the male offspring at ages 3-13 months. Significant reductions in baseline synaptic transmission were observed in hippocampal field potentials at all dose levels. This included reductions in synaptic transmission at the perchlorate dose that only marginally reduced (about 16 percent) circulating levels of thyroid hormone in dams (30 ppm, 4.5 mg/kg/day).

The Morris water maze failed to uncover spatial learning deficits in perchlorate-treated animals despite the observations of altered hippocampal synaptic transmission coupled with spatial learning impairments after thyroid hormone disruption induced by propylthiouracil (PTU) or methimazole noted in this report and in contemporary studies in perchlorate treated animals. Perhaps these differences are related to sex. This study examined only male offspring, while in the van Wijk *et al.* (2008) study discussed above, spatial memory effects were only seen in females. It may also be related to differences in the mechanism of toxicity or dosimetry compared to PTU and methimazole.

The lack of behavioral effects in the specific tasks used by Gilbert and Sui (2008) may also be a function of dose, degree of hormonal disruption, or the duration of prenatal exposure. Given the cognitive demands and sensitivity of the behavioral tasks, such outcomes are understandable. The failure of perchlorate to detrimentally impact hippocampal LTP is consistent with a lack of effect on behavioral plasticity and it is possible that the augmentation of PS (population spike) LTP is a reflection of an adaptive or compensatory response in cell physiology that aids in the reversal of learning deficits. Also, many other brain regions are engaged in the performance of simple learning tasks, and significant behavioral compensation may mask underlying behavioral deficits apparent earlier in development or revealed with more demanding cognitive tasks. Despite the lack of behavioral effects in the specific tasks used, the changes seen in synaptic transmission in adult offspring nevertheless provide evidence in

a rodent model that modest degrees of thyroid hormone reduction induced by perchlorate result in persistent alterations in brain function.

Human Studies of Infants Born to Mothers with Iodine Deficiency or Low Thyroid Hormone Levels

Many human studies have been published that demonstrate maternal thyroid deficiency during pregnancy affects neuropsychological development of the child. Some of the studies have shown that these effects may occur at thyroid hormone levels that have been traditionally considered to be within normal ranges.

Man and Jones, 1969. Man and Jones first reported that maternal hypothyroidism was associated with lower intelligence quotient scores (IQs) in 8-month-old infants. Hypothyroidism was defined in this study by two low serum butanol-extractable iodine test values during pregnancy or by one low serum butanol-extractable iodine value with clinical hypothyroidism. They found that 81 percent of 26 infants of women given thyroid replacement therapy after two low serum iodine tests were classified "normal," approximately the same percentage as for infants of euthyroid women. In contrast, only 48 percent of the 56 infants of women with two low serum iodine values who were not given adequate thyroid replacement therapy were "normal."

Glorieux *et al.*, 1985. These authors reported that children with significantly retarded skeletal maturation at the time of diagnosis, signifying hypothyroidism *in utero*, obtained lower global IQs than did children whose skeletal maturity was within normal limits.

Glorieux *et al.*, 1988. In a later study, Glorieux *et al.* studied 43 infants with congenital hypothyroidism and found that low T4 (<2 µg/dL) and retarded bone surface (<0.05 cm^2) measurements taken before therapy initiation were strongly correlated with mental development at 3, 5, and 7 years of age (Table 11).

Table 11. Mental Outcome in Infants with Congenital Hypothyroidism Relative to Newborn Risk Criteria (Glorieux *et al.*, 1988)

Age in years	T4 < 2 µg/dL and bone surface measures < 0.05 cm^2			T4 > 2 µg/dL and/or bone surface measures > 0.05 cm^2		
	n	Mean IQ	IQ distribution	n	Mean IQ	IQ distribution
3	17	91 ± 4[a]	(61 – 120)	40	103 ± 2	(81 – 140)
5	14	88 ± 3[b]	(60 – 109)	30	104 ± 2	(84 – 125)
7	16	86 ± 3[b]	(49 – 98)	27	102 ± 2	(75 – 128)

[a] $p < 0.01$ [b] $p < 0.001$

Rovet *et al.*, 1987. Similar findings have been reported by Rovet *et al.*, who studied intellectual and behavioral characteristics at 1, 2, 3, 4, and 5 years of age of 23 boys and 57 girls with congenital hypothyroidism. The children were

assigned to two groups based on degree of skeletal maturity at the time of diagnosis. Forty-five children with bone age <36 weeks were assigned to the delayed group; 35 with bone age 37 to term were assigned to the nondelayed group. Both groups were treated for congenital hypothyroidism and the initial starting dosages of L-thyroxine for the delayed and nondelayed were similar, 8.1 mg/kg and 7.8 mg/kg, respectively. Although most children with athyrosis were found in the delayed group, the group did not differ in birth weight, hormone levels, or family background. Hormone levels at diagnosis of both groups are shown in Table 12. Tests showed that although children in the delayed group performed within the normal range, their scores were significantly lower than those of the nondelayed group from age 2 years on. Perceptual-motor, visuospatial, and language areas were most affected.

Table 12. Hormone Levels at Diagnosis in Children with Delayed and Nondelayed Skeletal Maturity (Rovet *et al.*, 1987)

	Delayed (n = 45)	**Nondelayed (n = 35)**
	TSH (U/dL)	
Screening	136.1 ± 128.8	130.6 ± 78.6
Confirmation	112.5 ± 119.2	131.9 ± 100.5
	Thyroxine (T4) (µg/dL)	
Confirmation	5.1 ± 4.7	5.5 ± 3.9
1 month	11.0 ± 5.3	10.3 ± 5.7
3 months	12.0 ± 4.5	13.5 ± 3.9
6 months	13.6 ± 2.8	12.6 ± 3.2
9 months	12.4 ± 3.5	14.1 ± 5.3
12 months	12.7 ± 2.7	13.5 ± 2.3

Values represent mean ± standard deviation.

Vermiglio *et al.*, 1990. This study demonstrated that normal euthyroid children born to mothers from severe (area A) and less severe (area B) iodine deficiency regions in northeastern Sicily have a defective visual perceptual integrative motor ability. They studied 719 primary schoolchildren (366 males and 353 females) from these areas ranging from ages 6 to 12 years old (conceived and born between 1975 and 1981). A control group consisted of 370 age-matched schoolchildren from an iodine-sufficient area where rates of goiter were lower (area C). The prevalence of goiter in the schoolchildren of these areas and the daily urinary iodine excretion in the general population between 1976 and 1984 are given in Table 13.

Table 13. Prevalence of Goiter in Schoolchildren and Daily Urinary Iodine Excretion in Adults (1976-1984) in the Study Areas (Vermiglio *et al.*, 1990)

Study area	Total population	Prevalence of goiter in the schoolchildren (%)	Daily urinary iodine excretion (µg/day)[a]
Area A (with endemic cretinism)	7,432	70.3 (708)	24.3 ± 16.4 (55)
Area B (without endemic cretinism)	10,992	45.9 (763)	31.3 ± 18.7 (150)
Area C (control area)	9,730	8.9 (370)	82.4 ± 43.0 (30)

[a]Mean ± standard deviation; the number of observations is given in parentheses.

Variable degrees of thyroid enlargement were found in 205 of the 719 (28.5 percent) children included in the study from areas A and B (area A: 30.4 percent, visible goiter 15.2 percent; area B: 26.5 percent, visible goiter 16.3 percent). Furthermore, defective visual perceptual integrative motor ability (the Bender Gestalt test) was significantly higher in children from area A (14.4 percent) and area B (13.1 percent) than in those from area C (3.5 percent) (Table 14).

Table 14. Number of Defective, Borderline, and Nondefective Schoolchildren as Assessed by the Bender Gestalt Test (Vermiglio *et al.*, 1990)

Performance on Bender[a]	Area A	Area B	Area A+B	Area C
Defective	53 (14.4)	46 (13.1)	99 (13.8)	13 (3.5)
Borderline	57 (15.5)	67 (19.1)	124 (17.2)	14 (3.8)
Nondefective	258 (70.1)	238 (67.8)	496 (69.0)	343 (92.7)
Total	368 (100)	351 (100)	719 (100)	370 (100)

Percent in parentheses.
[a]Performance scores: Defective = below -1 standard deviation from average score of normal children of the same age; Borderline = –1 standard deviation from average score; Nondefective = higher than –1 standard deviation from average score.

The statistical comparisons for the Bender Gestalt Test scores across the different areas were as follows:

Defective:

Area A vs. area B: Chi-square (χ^2) =2.75; p=0.87

Areas A+B vs. area C: χ^2 =36.25; p<0.000001

Borderline:

Area A vs. area B: χ^2 =1.22; p=0.27;

Areas A+B vs. area C: χ^2 =77.55; p<0.000001

Vermiglio *et al.* (1990) also reported higher frequency of neuromuscular and neurosensorial abnormalities among children from areas A and B (a combined overall prevalence of 18.9 percent) compared to those from area C. The Terman Merrill test of general intellectual aptitude was administered to 96 of the 99 "defective" children and 62 of the 124 borderline children from both areas A and B (Table 14). Ninety-one of the 96 "defective" children (94.8 percent) had IQs lower than 90, as did 35 of the 62 borderline (56.4 percent) children (Table 15).

Table 15. Performance on the Terman Merrill Test of General Intellectual Aptitude Administered to Schoolchildren with Defective or Borderline Performance Scores on the Bender Gestalt Test (Vermiglio *et al.*, 1990)

Performance on Bender test	Intelligence Quotient Score		
	< 90	90-95	96-100
Defective (n = 96)	91	5	0
Borderline (n = 62)	35	23	4
Nondefective (n = 12)	0	10	2

Statistical analysis: χ^2 =52.1; p<0.0000005.

Despite the adverse effects described above, the serum T3 and T4 levels of the children from area A and area B were within the normal range. This suggests that serum T3 and T4 are not completely accurate indicators of the neurological damages that may be caused by iodine deficiency.

Tillotson *et al.*, 1994. These authors reported the results of a prospective study of psychological outcomes of 361 children with congenital hypothyroidism after five years of treatment and follow-up. They also selected 315 children as controls, matched for school attended, sex, age (within three months), language spoken at home, and social class defined by occupation of the family breadwinner. The severity of the hypothyroidism was assessed using T4 measurements collected at the time of diagnosis (median age 17 days; range 0-114). The study showed that among children with congenital hypothyroidism and given early treatment, those with plasma T4 concentrations of less than 42.8 nmol/L (3.3 µg/dL) at the time of diagnosis had a global deficit in mean IQ of 10 points, while those with higher T4 levels at the time of diagnosis had no deficit.

Bleichrodt and Born, 1994. These authors performed a meta-analysis on 18 studies of iodine deficiency and mental development. Studies included those with information on the general cognitive functioning of children and adults living in iodine-deficient areas and provided the necessary statistical data. Three studies were excluded from the analysis because the composition of the groups studied was different (they were composed exclusively of school children). In the meta-analysis of the effects of iodine deficiency on cognitive development, a large effect size was found with a d-value of 0.90. This means that the mean scores for the two groups (the iodine-deficient group and the non-iodine-deficient group) were 0.90 of a standard deviation (or 13.5 IQ points) apart.

Pop *et al.*, 1999. Pop *et al.* (1999) reported that low maternal fT4 concentrations in apparently healthy women during early gestation are associated with an increased risk of impaired neurodevelopment in the infant. They studied a group of 291 pregnant women in an iodine-sufficient area (in and around the city of Veldhoven, Netherlands) between January and November, 1994. No women in the study group were receiving antithyroid drugs or thyroid hormones. Maternal fT4, TSH, and thyroid peroxidase antibodies were assessed at 12 and 32 weeks' gestation, and neurodevelopment of 220 healthy children was assessed at 10 months of age. The authors found that children of women with fT4 levels below the 5th (<9.8 pmol/L, n=11) and 10th (<10.4 pmol/L, n=22) percentiles at 12 weeks' gestation had significantly lower scores on the Bayley Psychomotor Developmental Index (PDI) scale at 10 months of age than children of mothers with higher fT4 values. These findings are shown in Table 16. The mean of PDI scores in all subjects was 100, so the decreases seen here represent about a 7-14 percent decrease. The unadjusted odds ratio for impaired psychomotor development (defined as a one standard deviation decrease from the mean) for fT4 in the lower 10th percentile was 3.6 (95% CI, 1.1-12.1). This rose to 5.8 (95% CI, 1.3-12.6) following adjustment for alcohol use, anti-thyroid antibodies, depression, education and other factors.

Although the mean fT4 value for subjects in the lower 10th percentile of fT4 is not given (only the percentile cut-off points are provided), they can be estimated from Table 1 and Figure 2 of the paper. The mean fT4 for subjects in the lower 10th percentile is approximately 9.8 pmol/L compared to a mean fT4 of a little over 13.1 in the remaining subjects. This represents a difference of about 25 percent. Thus, a 25 percent lower maternal fT4 was associated with about a 7 percent decrease in PDI scores in children.

Evidence of a linear association between maternal fT4 and child PDI scores was seen in those children with maternal fT4 levels in the lower 10th percentile ($r = 0.46$, $p = 0.03$). No correlation was found between maternal thyroid hormone levels at 32 weeks' gestation and PDI scores. All children had normal T4 and TSH values. Six of the 22 women with fT4 values in the lower 10th percentile had high levels of anti-thyroid antibodies.

Table 16. Maternal fT4 Levels at 12 Weeks Gestation and PDI Scores in Children at 10 Months of Age (Pop *et al.*, 1999)

Low Maternal fT4 Group[a]	Difference in PDI scores	95% CI
Lower 5th percentile (n = 11)	14.1	5.9-22
Lower 10th percentile (n = 11)	7.4	1.1-13.9

[a] These groups were compared to all the children with higher maternal fT4 levels.

Haddow *et al.*, 1999. This study involved measurements of TSH, fT4, and T4 in 25,216 pregnant women in Maine at 17 weeks of gestation. Three subgroups of women were selected from this large cohort: 47 women with TSH levels in the upper 99.7th percentile, 15 women with TSH levels in the upper 98th to 99.6th percentile, and 124 women with TSH levels below the upper 98th percentile (the "controls"). Measurements of thyroid function of the women in the study are shown in Table 17. Notably, the fT4 and T4 values of many of the women in the high TSH groups are within normal reference ranges. The researchers then administered 15 neuropsychological tests to the children of these women at ages seven to nine years old. The tests included assessment of intelligence, attention, language, reading ability, school performance, and visual-motor performance. The staff giving the tests did not know whether the children's mothers were women with hypothyroidism or control women. They found that the children of the 62 women with high serum TSH concentrations (all those above the 98th percentile) performed less well on all 15 tests. Mean IQ scores, as measured by the Wechsler Intelligence Scale for Children, were 4 points lower in the children of women with high TSH levels compared to the children of the control mothers (103 versus 107, $p = 0.06$). Of the 62 women with elevated TSH levels during pregnancy, 48 were not treated for the condition during the pregnancy. The full-scale IQ scores of their children averaged 7 points lower than those of the 124 matched control children (100 versus 107, $p = 0.005$). Results were controlled for education, maternal age, sampling time, sample storage time, and gender. The effect size seen in this study is similar in magnitude to that seen in Pop *et al.* (1999). That is, a difference in maternal T4 or fT4 of about 25 percent was associated with about a 4-7 percent decrease in IQ.

Sixty-four percent of the women with high TSH levels during pregnancy went on to be diagnosed with clinical hypothyroidism over the next 10 years. None of the children were diagnosed as hypothyroid as newborns. Haddow *et al.* (1999) concluded that even mild and probably asymptomatic hypothyroidism in pregnant women can adversely affect their children's subsequent performance on neuropsychological tests.

Table 17. Measurements of Thyroid Function in the Study Women during Pregnancy (Haddow *et al.*, 1999)[a]

Variable	Hypothyroidism (n = 62)	Controls (n = 124)
Serum TSH (mU/L)	13.2 ± 0.3[b]	1.4 ± 0.2
Serum T4 (µg/dL)	7.4 ± 0.1[b] (95.2 nmol/L)	10.6 ± 0.1 (136.4 nmol/L)
Serum fT4 level (ng/dL)	0.71 ± 0.1[b] (9.1 pmol/L)	0.97 ± 0.07 (12.5 pmol/L)

[a]Values are geometric means ± the logarithmic standard deviation.
[b]$p<0.001$ for the comparison with the control women.

Pop *et al.*, 2003. In another study, Pop *et al.* (2003) reported that a low maternal fT4 during early pregnancy was associated with a delay in infant neurodevelopment. In this study, the researchers followed 115 children and their mothers for two years. Maternal levels of fT4 and TSH were assessed at 12, 24, and 32 weeks of gestation. "Cases" (n = 57) were defined as children of mothers who had fT4 levels in the lower 10th percentile at 12 weeks of gestation and "controls" (n = 58) were defined as children of mothers who had fT4 levels in the upper 50th to 90th percentiles at 12 weeks gestation. Mothers of cases and controls were matched on parity and gravidity. Cases and control families were similar with respect to education, breast feeding, smoking, alcohol use, and income. Mothers with thyroid disease, depression, and TSH levels outside of normal ranges were excluded. Child mental and motor functions were assessed using the Bayley Scales of Infant Development at ages 1 and 2. The results are shown in Table 18. Case children scored 8-10 points lower on the mental and motor scales than control children.

Table 18. Mental and Motor Scale Scores (± Standard Deviation) in Children of Mothers with Low (Cases) and High (Controls) Levels of fT4 at 12 Weeks of Gestation (Pop *et al.*, 2003)

Age	Cases	Controls	Difference (95% CI)	p-value
One year				
Mental score	95 ± 15	105 ± 14	10 (4-16)	0.004
Motor score	91 ± 15	99 ± 14	8 (3-12)	0.02
Two years				
Mental score	98 ± 15	106 ± 14	8 (4-12)	0.02
Motor score	92 ± 16	102 ± 16	10 (6-16)	0.005

All children had normal Apgar scores at birth and normal screening results for congenital hypothyroidism on the seventh postpartum day. Pop *et al.* (2003) observed that children of women who had low fT4 levels during early gestation and who exhibited a further decrease of fT4 during gestation had the lowest mental and motor scores. In contrast, children whose mothers had a low fT4 at 12 weeks gestation, but whose fT4 levels increased during later gestation, did not show any delay in development. Maternal fT4 levels at 24 and 32 weeks gestation were not associated with decreases in childhood motor or mental scores.

The mean fT4 levels at 12 weeks of gestation was 11.5 pmol/l in the case mothers and 17.0 pmol/l in the control mothers (estimated from Figure 2 in Pop *et al.*, 2003), about a 32 percent difference. Thus, a 32 percent difference in fT4 was associated with an 8-10 point drop in mental and motor scores. This is about the same magnitude of effect as seen in Pop *et al.* (1999) and Haddow *et al.* (1999). Importantly, the cut-off point used to define cases (the 10th percentile)

is above the level traditionally used to define low fT4 levels (the 2.5th or 5th percentiles), thus many of the cases had maternal values of fT4 that would traditionally be defined as normal. Figure 3 of Pop *et al.* (2003) presents a scatter plot of maternal fT4 values and childhood mental and motor scores in the case children at 2 years of age. Evidence of a linear relationship is present for both mental scores ($r^2 = 0.13$, $p = 0.006$) and psychomotor scores ($r^2 = 0.23$, $p = 0.001$). These r^2 values suggest that maternal fT4 accounts for a statistically significant fraction of the total variance in these scores.

Klein *et al.*, 2001. In a follow-up investigation, Klein *et al.* (2001) studied serum TSH concentrations of pregnant mothers at a mean of 17 weeks gestation and the standard neuropsychological testing results of their offspring at a mean age of 8 years. They found an inverse correlation between the severity of maternal hypothyroidism and IQs in the offspring. The researchers divided the mothers and their offspring into three groups: group 1, 124 control mothers with TSH concentrations <98th percentile; group 2, 28 mothers with TSH concentrations between the 98th and 99.85th percentile; group 3, 20 mothers with TSH concentrations ≥99.85th percentile. Mothers treated for hypothyroidism during pregnancy were excluded from the study. The mean neuropsychological test score (± standard deviation) for the children of the 124 control mothers was 107 (± 12). Means (and standard deviations) for the children in groups 2 and 3 were 102 (± 15, $p > 0.05$ compared to group 1) and 97 (± 14, $p = 0.003$ compared to group 1), respectively. The incidences of IQs greater than one standard deviation below the control mean were 15 percent, 21 percent, and 50 percent for the children in group 1, group 2, and group 3, respectively. In a related study, the same authors also reported spontaneous abortions and intra-uterine fetal deaths were more than five times as common in the mothers with TSH concentrations above the 98th percentile than in control mothers with TSH concentrations below the 98th percentile.

Kooistra *et al.*, 2006. This study involved the children of 108 pregnant women who had fT4 values below the 10th percentile at 12 weeks gestation ("cases") and 96 pregnant women who had fT4 values in the 50th to 90th percentiles at 12 weeks gestation ("controls"). People with clinical disease were excluded. Case and control mothers were matched on parity and gravidity. Newborn development was assessed at 3 weeks of age using the Neonatal Behavioral Assessment Scale. Mean thyroid hormone levels in the cases and controls are shown in Table 19.

Table 19. Mean (± Standard Deviation) Maternal fT4 and TSH, and the Proportion with Anti-thyroid Antibodies at 12 Weeks Gestation (Kooistra *et al.*, 2006)

	Cases	Controls	p-value
fT4 (pmol/L)	11.4 ± 1.0	17.0 ± 0.9	< 0.001
TSH (mIU/L)	1.6 ± 1.0	1.1 ± 0.8	< 0.001
Anti-thyroid Antibodies	16.7%	4.2%	< 0.01

A statistically significant difference between case and control children was only seen in the orientation scores. In the linear regression analysis with orientation score as the dependent variable, a statistically significant association was seen for case status ($\beta = 0.173$, $p = 0.02$). The researchers also performed a logistic regression analysis where a "low orientation score" was used as the dependent variable. This was defined as subjects who had scores less than one standard deviation below the mean score. The odds ratio for a low score in controls versus cases was 0.17 (95% CI, 0.05 - 0.51). This was adjusted for maternal smoking, alcohol use, gestational age, depression, gender of the child, and maternal education. No difference was seen between case and control maternal fT4 or TSH during the 2nd or 3rd trimester or in the newborns' heel stick T4. No associations were seen between Neonatal Behavioral Assessment Scale scores and TSH or fT4 later in pregnancy.

This study is different from some of the other studies discussed above because the children were very young at the time their cognitive status was assessed. The authors argue that this is an advantage because it limits the impact of external socioeconomic factors that can affect a child's cognitive development as they age. The authors also note a potential major disadvantage: a test given this early may not be predictive of development later in life.

Vermiglio *et al.*, 2004. This was a 10-year prospective study which included 16 healthy women and their offspring from a moderately iodine deficient area (area A, mean urinary iodine levels = 48.1 µg/day) and 11 healthy control women and their offspring from a marginally iodine sufficient area (area B, mean urinary iodine levels = 95.2 µg/day) in Northeastern Sicily. Maternal levels of thyroid hormones were assessed at 8, 13, and 20 weeks of gestation. In the offspring, IQ scores and tests for attention deficit and hyperactivity disorder (ADHD) were done at ages 8-10 years. IQ scores were obtained using the Wechsler Intelligence Scale for Children, 3rd Edition, and tests for ADHD were derived from the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition.

All children were euthyroid at delivery, at ages 18-36 months, and at ages 8-10 years. ADHD was diagnosed in 11 of 16 children from the low iodine area and in none of the 11 children from the moderate iodine area. The mean IQ score in the children from the low iodine area was 18 points lower than the mean score in the

children from the high iodine area (92.1 ± 7.8 versus 110 ± 10, $p < 0.00005$). Maternal fT4, T4, and TSH levels at 8, 13, and 20 weeks were presented graphically and showed that fT4 and T4 levels were roughly 10-20 percent lower for those children from the low iodine area (A) compared to children from the moderate iodine area (B). Eight of the 16 women from the low iodine area had fT4 values that were lower than normal for the gestational week. Seven of these eight gave birth to 8 of the 11 children subsequently diagnosed with ADHD. Only one woman from the control area had a gestational fT4 value outside of normal ranges.

When all children were grouped together, a strong correlation was seen between the child's IQ score and maternal fT4 ($r = 0.56$, $p < 0.005$) and TSH ($r = -0.63$, $p < 0.001$). These results and the graph of these data (Figure 3 in Vermiglio *et al.*, 2004) suggest that the relationship between T4 and IQ extends into the normal ranges of T4.

Bath *et al.*, 2013. In this study, mother-child pairs (n=958) in the Avon Longitudinal Study of Parents and Children in southwest England were used to evaluate the relationship between maternal urinary iodine concentrations measured in the first trimester of pregnancy (median 10 weeks, collected in 1991-92) and the IQ (abbreviated form of the Wechsler Intelligence Scale for Children) and reading ability (Neale Analysis of Reading Ability) of the offspring measured at ages 8 and 9 years. The odds ratio for having a verbal IQ score in the lower quartile in those whose mothers had a urinary iodine to creatinine ratio of <150 µg/g, compared to those whose mothers had a urinary iodine to creatinine ratio of ≥150 µg/g, was 1.58 (95% CI, 1.09-2.30, p=0.02). Corresponding odds ratios were 1.69 (95% CI, 1.15-2.49) for reading accuracy and 1.54 (95% CI, 1.06-2.23) for reading comprehension. Evidence of dose-response trends were seen when subjects were divided into three iodine-creatinine ratio groups. The odds ratios for performance IQ (odds ratio = 1.22; 95% CI, 0.86-1.72) and words read per minute (odds ratio = 1.20; 95% CI, 0.83-1.74) were above 1.0, but not statistically significant. Adjustments for over 20 different potential confounding variables including maternal age, parenting score (a seven factor measure of cognitive stimulation at age 6 months), gender, birth weight, breastfeeding, smoking, alcohol consumption, parental education, and housing status had little impact on most results. Strengths include the longitudinal design, the fairly large sample size, and availability of data on a large number of potential confounders. Potential weaknesses include the possibility that despite the large amount of data on potential confounders, it is still possible that some important determinants of child cognition were not accounted for. This seems unlikely given the fact that odds ratios changed only slightly with the many adjustments that were done. Another potential weakness was the use of a single measurement of urinary iodine to represent long-term iodine status, although this would most likely bias results to the null. Overall, these data provide some evidence that relatively low iodine status during pregnancy can impact the child's cognitive development.

Other studies: Not all studies have found associations between fetal hypothyroidism and impaired brain development. Several studies examined children exposed to antithyroid drugs such as carbimazole, propylthiouracil, or thiamazole *in utero* and did not find an association between the treatment and the later intellectual and somatic development of the children (McCarrol *et al.*, 1976; Burrow *et al.*, 1978; Messer *et al.*, 1990). The statistical power of these studies may be limited since they had relatively small sample sizes and the dosage and timing of the treatment were not known in many cases. In the study reported by Burrow *et al.* (1978), most of the treated children were exposed to propylthiouracil *in utero* during the third trimester, and only four were exposed during the first and second trimester. The studies reported by Burrow *et al.* (1978) and Messer *et al.* (1990) were retrospective studies in which maternal T4 levels during the first and second trimesters were not known. It is possible that the treated women had normal T4 levels during the early part of their pregnancies.

Fenzi *et al.* (1990) conducted neuropsychological assessments on a group of 384 school children (aged 6-14 years) residing in an area of known iodine deficiency (Tuscany, Italy). A group of 352 sex- and age-matched schoolchildren from an iodine sufficient area was used as a control group. Goiter prevalences in the endemic and control areas were 51.9 percent and 5.6 percent, respectively. No statistically significant differences in serum total T4, total T3, TSH levels between the endemic and control areas were found. Serum thyroglobulin values were higher in the iodine-deficient area. Global neuropsychological performance and cognitive levels were similar between a group of 50 schoolchildren from the endemic area and another group of 50 schoolchildren from the control area, matched for age, sex and socioeconomic conditions. However, Fenzi *et al.* (1990) also found that some marginal impairment, with particular regard to motor-perceptual functions, was present in areas of moderate iodine deficiency.

The New England Congenital Hypothyroidism Collaborative Program (1981) found that there was no correlation of eventual IQs with the severity of thyroid dysfunction or with the results of biochemical tests at the time treatment was begun, provided it was begun before clinical hypothyroidism appeared. A diagnosis of hypothyroidism was made when an infant's initial blood concentration of T4 was two or more standard deviations below the mean for newborn infants (6 µg/dL or less) and circulating TSH concentrations were elevated on repeated occasions. Three hundred thirty-six thousand newborn infants in Connecticut, Maine, Massachusetts, New Hampshire, and Rhode Island born between January 1, 1976 and June 30, 1978 were screened. Sixty-three infants were diagnosed with hypothyroidism and treated with L-thyroxine in doses sufficient to maintain circulating T4 concentration between 10 and 14 µg/dL during the first year of life and between 8 and 11 µg/dL thereafter. The control group consisted of 57 euthyroid children who had low T4 and normal TSH concentrations on neonatal screening. The revised Stanford-Binet examination was given to all the test subjects at 3 or 4 years of age. The authors reported that the mean IQ for the hypothyroid infants with adequate thyroid treatment was

106±16 and the mean for the controls was 106±15. They also reported that half of the patients with the lowest IQs (more than one standard deviation below the mean) had normal bone maturation. It is important to note that the results of Pop *et al*. (1999) indicated that it is the low maternal T4 level during early gestation (around week 12) that is associated with impaired neurodevelopment in the infant. It is possible that T4 levels at birth are not a perfectly accurate indicator for thyroid related neurodevelopmental deficiencies occurring in early gestation.

Liu *et al*. (1994) examined the IQs of eight children (Group 1) who were born to mothers that were hypothyroid during the first trimester of pregnancy. Maternal free T4 values at the 5^{th} to 10^{th} gestation weeks ranged from 2.3 to 6.3 pmol/L (normal range, 11.6 to 24.5 pmol/L) in six of the eight cases. In the other two cases, maternal total T4 values were 52.8 and 30.9 nmol/L (normal range, 92.7 to 218.8 nmol/L). TSH levels of the eight mothers at that time ranged from 25 to 190 mU/L (normal range < 5 mU/L). Maternal T4 and TSH levels became normal after T4 supplementation by 13 to 28 weeks of gestation. Seven of the eight children had nine siblings who had not been exposed to maternal hypothyroidism throughout gestation (Group 2); they were used as controls. Ages of the children in groups 1 and 2 at the time of IQ examination were 4 to 10 years in group 1 and 4 to 15 years in group 2. The investigators reported that all children in group 1 showed normal IQs. There was no statistically significant difference in the mean IQ between the children in group 1 who had siblings (112±11) and their siblings in group 2 (106±8). The study is limited by the small sample size. The administration of T4 supplement to hypothyroid mothers at 13 weeks of gestation might have averted adverse neurological development in the fetuses.

Summary of Data on Thyroid Hormones and Childhood Cognitive Development

While not all studies have reported clear links between maternal or neonatal levels of thyroid hormone and the subsequent neurological development of the child, at least five studies have. Studies by Haddow *et al*. (1999), Pop *et al*. (1999, 2003), Kooistra *et al*. (2006), and Vermiglio *et al*. (2004) have all reported statistically significant deficits in measures of childhood cognition and development in groups whose maternal gestational levels of T4 or fT4 include values that have traditionally been considered to be within normal reference ranges. For example, in Kooistra *et al*. (2006), the mean 12-week gestational fT4 in the low fT4 group was 11.4 pmol/L. Since the reference range given by the authors was 8.7-19.6 pmol/L, it is likely that the majority these mothers had fT4 values within the reference range. In addition, all of these studies excluded women with overt clinical thyroid disease, so the effects identified are occurring in the children of women who are asymptomatic. The animal studies by Auso *et al*. (2004), Gilbert and Sui (2008), Lavado-Autric *et al*. (2003), and others support the biologic plausibility that relatively mild decreases in maternal thyroid hormone levels in gestation can cause significant and permanent neurological changes in the offspring.

Some of the effects seen in the human studies are difficult to compare from one study to the next since different outcome measures are used in different studies. Despite this, the magnitudes of the effects seen in these studies seem to be markedly consistent across at least several of them. Table 20 shows the effect sizes in four of these studies. In each, a difference in maternal fT4 or T4 of about 11-32 percent is associated with a decrease in the cognitive development score in the offspring of about 7-16 percent.

Table 20. Comparison of Four Studies of Maternal T4 or fT4 in the First Trimester and Subsequent Child Neurologic Development

	Haddow *et al.*, 1999	Pop *et al.*, 1999	Pop *et al.*, 2003	Vermiglio *et al.*, 2004	Averages
Gestation week	12 weeks	12 weeks	12 weeks	8-13 weeks	
Thyroid measure	T4 (ng/dL)	fT4 (pmol/L)	fT4 (pmol/L)	fT4 (pmol/L)	
Low thyroid group	7.4	9.8[a]	11.5[a]	13.9	
Normal thyroid group	10.6	13.1[a]	17.0[a]	15.7	
Percent difference	30.2%	25.2%	32.4%	11.5%	24.8%
Outcome measure	IQ	PDI	MDI & PDI[b]	IQ

Alterations in Thyroid Hormones and Effects on Serum Lipids and Other Biomarkers of Cardiovascular Disease Risk.

Effects on childhood cognitive development are not the only adverse effects that have been linked with relatively small changes in thyroid hormone levels. The following discussion focuses on the possible cardiovascular effects of relatively minor changes in thyroid hormone levels.

Asvold *et al.*, 2007. This was a cross-sectional population-based study of TSH and serum lipid levels in 30,656 subjects from Norway. All subjects had no known thyroid disease and all had TSH levels within normal reference ranges (0.50 – 3.5 mU/l). The researchers found a linear and statistically significant (p for trend < 0.001) increase in total serum cholesterol, LDL cholesterol, non-HDL cholesterol and triglycerides, and a linear decrease in HDL cholesterol (p for trend < 0.001), with increasing TSH. Results were adjusted for age, smoking, and time since last meal. Adjustments for daily medication use, month of serum collection, diabetes mellitus, heart disease and stroke had no substantial impact on results. Although the changes were associated with very low p-values, the magnitudes of the changes were relatively small. For example, the mean LDL in the lowest TSH group (TSH = 0.50-0.99 mU/l) was 4.11 mmol/L while the mean

LDL in the highest TSH group (3.0-3.5 mU/l) was 4.34 mmol/L, about a 5 percent change. Although this level of change might be considered small on an individual basis, a 5 percent shift in cholesterol levels in a large population could represent a large increase in the population risks of diseases associated with cholesterol (e.g., heart disease and stroke). The results of this study are supported by other smaller studies which also reported similar effects for thyroid hormone levels within normal reference ranges (Pallas *et al.*, 1991; Bakker *et al.*, 2001; Michalopoulou *et al.*, 1998).

Canaris *et al.*, 2000. This was a cross-sectional study of serum lipids, thyroid hormones, and reported history of thyroid disease in 25,862 self-selected people who attended a statewide health fair in Colorado. Subjects were divided into five groups based on their TSH and T4 levels, and mean levels of serum lipids were determined for each group. The TSH and T4 levels used to define these groups and the mean lipid levels seen in each group are shown in Table 21. Statistically significant trends were seen across groups for total cholesterol (p-trend < 0.001), LDL cholesterol (p-trend < 0.001), and triglycerides (p-trend = 0.02), but not for HDL cholesterol. It is unclear whether these results were adjusted for any other variables although the authors did note that levels of estrogen use were similar across all thyroid hormone categories. Although the presence of a linear trend within the euthyroid group was not specifically evaluated, the overall trend across all of the thyroid hormone groups suggests that a trend is likely to occur over the entire range of TSH values.

Table 21. Mean Lipid Levels in Various Thyroid Groups in Canaris *et al.*, 2000

	Group definitions		Cholesterol (mmol/L)			
	TSH (mIU/L)	T4 (nmol/L)	Total	LDL	HDL	TGs
Hypothyroid	> 5.1	< 57.9	6.5	4.4	1.4	2.0
Subclinical hypothyroid	> 5.1	≥ 57.9	5.8	3.8	1.4	1.8
Euthyroid	0.3-5.1	--	5.6	3.6	1.3	1.7
Subclinical hyperthyroid	0.01-<0.3	--	5.4	3.4	1.5	1.6
Hyperthyroid	≤ 0.01	--	5.2	3.4	1.3	1.6

Abbreviations: TGs, triglycerides.

Dullaart *et al.*, 2007. This was a cross-sectional study of carotid artery intima media thickness (IMT) in 44 men and 34 women who all had fT4 (11.0-19.5 pmol/L) and TSH (0.5 mU/L -4.0 mU/L) levels within normal reference ranges. IMT is a subclinical measure of potential atherosclerosis. In multiple linear regression analyses adjusted for age, gender, pulse pressure, body mass index,

and HDL cholesterol, IMT was inversely related to fT4 (β = -0.19, p = 0.046), but not to TSH or the presence of anti-thyroid antibodies.

While several previous studies have reported that overt thyroid disease is associated with increased cardiovascular disease risks (Boelaert and Franklyn, 2005; Vanhaelst *et al*., 1967; Becker, 1985), the findings from this study and the studies of Asvold *et al*. (2007) and Canaris *et al*. (2000), all provide evidence that cardiovascular disease risk is also affected by decreases in thyroid hormone levels within normal reference ranges.

4. TOXICOLOGICAL EFFECTS IN HUMANS

The primary action of perchlorate in the human body is that it blocks iodide uptake in the thyroid gland. The function of the thyroid gland is the production of thyroid hormone. Iodide is a key component in the structure of thyroid hormone, and by blocking its uptake into the thyroid gland, perchlorate can potentially cause a decreased production of thyroid hormone.

As perchlorate competitively blocks iodide from entering the thyroid gland, many of the adverse effects of perchlorate exposure in the low dose range are expected to be similar to those of iodine deficiency. For this reason, an overview of some of the adverse health effects of iodine deficiency was provided in the chapter "Adverse Effects of Thyroid Hormone and Iodine Deficiency."

Developmental and Reproductive Toxicity

Studies of the impacts of perchlorate on thyroid hormone levels in newborns or children are discussed in this section. Impacts in adults, including pregnant women, are discussed in the following section.

Several studies have assessed the association between maternal exposure to perchlorate in drinking water during pregnancy and changes in thyroid hormone levels in newborns. Most of these studies used thyroid hormone levels that were collected as part of state-mandated screening programs for congenital hypothyroidism. Although these programs typically involve measuring thyroid hormone levels at any time in the first two weeks after birth, levels collected in the first 1-2 days after birth may be particularly important for several reasons. First, studies have shown that subtle changes in thyroid hormone levels may have greater impacts on brain development if they occur in the fetal period than if they occur later (i.e., in the newborn or young child) (Pop *et al.*, 2003; Kooistra *et al.*, 2006). Since thyroid hormone levels generally cannot be measured in the fetus during pregnancy in humans, the best practicable way to assess any effect in the fetus caused by perchlorate exposure to the mother during pregnancy would be to measure thyroid hormone levels in the child as soon after birth as possible (e.g., within the first 1-2 days after birth). Second, most of the human studies on newborn thyroid function and maternal perchlorate exposure categorized exposure based on the concentration of perchlorate in the mother's residential drinking water *during* pregnancy, not on the actual perchlorate intake of the newborn *after* birth. This is important since the half-lives of both perchlorate and thyroid hormones in newborns are fairly short (less than 24 hours) (Greer *et al.,* 2002; Van den Hove *et al.*, 1999). As such, any effect that the mother's perchlorate exposure during pregnancy might have on the fetal thyroid should be seen within the first 24 hours after birth (e.g., within the thyroid hormone and perchlorate half-lives). But, they may not be seen at a later time if perchlorate exposure changes at birth. For example, the newborn may be fed an

infant formula with a different perchlorate concentration than that of the drinking water used by the mother during pregnancy. Perchlorate exposure may also change after birth in breast-fed infants if the mother uses water from the hospital or bottled water that has a different perchlorate concentration than the residential water used before birth.

The exposure to the infant might also be affected by the different kinetics of transplacental versus breast milk transfer of perchlorate. Since most of these studies based exposure status solely on the water source used by the mother before birth, any change in exposure in the child after birth could lead to a misclassification of exposure that would bias results towards the null and could cause any true effect to appear to diminish relatively soon after birth. Since the half-life of thyroid hormone in the child is short, this bias would most likely begin to occur within 24 hours after birth and become stronger thereafter. Because of this potential bias, our evaluation of these studies adds an additional emphasis on thyroid hormone measurements collected within the first 24 hours after birth.

Clinical Studies of Developmental and Reproductive Toxicity

Crooks and Wayne (1960) administered potassium perchlorate at 600 to 1,000 mg/day to a group of pregnant women that were suffering from hyperthyroidism and observed a very slightly enlarged thyroid in 1 of the 12 infants born to the mothers. They also reported that the enlarged thyroid returned to normal size in six weeks, and no other abnormalities were observed. Several key parameters were not provided in the paper: detailed dosage information, time of perchlorate treatment in relation to the gestation period, thyroid function of the newborns, and the neurological as well as behavioral development of the offspring. Furthermore, interpretation of the result is made difficult by the fact that the women were suffering from thyrotoxicosis (excess quantities of thyroid hormones).

Epidemiologic Studies of Developmental and Reproductive Toxicity

DHS, 1997. A preliminary health review of a potentially perchlorate-exposed area of Rancho Cordova, CA by the California Department of Health Services (DHS, 1997) included an analysis of several state databases for possible perchlorate-related adverse health effects. Analysis of newborn thyroid hormone data for the period 1985 through 1996 did not indicate a positive correlation between residence in potentially perchlorate-exposed areas and neonatal hypothyroidism. The TSH levels of neonates with initially low T4 levels in the potentially exposed areas were found to be statistically lower than those in the control areas, contrary to what was expected.

Kelsh *et al.*, 2003. This investigation used the California Newborn Screening database to study the thyroid health of newborns whose mothers resided in the city of Redlands, California during the years 1983 through 1997. Perchlorate at variable levels has been detected in groundwater wells in this city. The

outcomes assessed were neonatal primary congenital hypothyroidism (PCH) and elevated neonatal serum levels of TSH (> 25 µU/mL). PCH is a severe condition, usually caused by a missing or partially missing thyroid gland in the child. It is generally associated with very large increases in TSH (e.g., > 25 µU/mL) and often requires treatment with thyroid hormone to prevent severe neurologic and physical growth deficits. TSH measurements were only collected when T4 levels were low (typically below 9 µg/dL or in the lowest five percent of the remaining daily tray samples). PCH was defined as an elevated TSH plus a physician's confirmatory diagnosis. Newborns of San Bernardino and Riverside counties, excluding newborns from Redlands and other communities where perchlorate has been detected, were used as the comparison group. The Colorado River is one of the water sources of Riverside County, so the water serving some of the "unexposed" comparison group may have been contaminated with perchlorate. Perchlorate exposure in the comparison areas would most likely bias any true associations towards the null. There is little information about the perchlorate levels in the drinking water in this area during the study period since the detection limit of perchlorate in water before 1997 was about 400 ppb. In the 2001 and 2002 Consumer Confidence Reports, the City of Redlands reported that the concentrations of perchlorate in its water system ranged from non-detect to 9 ppb, with an average concentration below 1 ppb. However, the California Department of Public Health reported perchlorate levels in Redlands wells in 1997 ranged from 4 ppb to 130 ppb, although it is unknown how much water from the high exposure wells was used for drinking.

Kelsh *et al*. (2003) found no increase in the prevalence of PCH in Redlands newborns over the 15-year study period, although there were only two cases of PCH reported in Redlands during this time. Because there is a normal transient surge in neonatal TSH levels immediately after birth, measuring TSH levels within the first few hours of birth can lead to a high rate of false positives in screening programs for PCH. Because of this, the researchers did further analyses, which excluded subjects who had TSH measurements collected within the first 18 hours of birth. However, as discussed above, measurements collected in the first day after birth may actually be the most relevant, and as discussed below, the post-natal surge in TSH does not necessarily invalidate associations identified between perchlorate and neonatal thyroid hormone levels during this time.

The odds ratio for an elevated TSH for Redlands compared to San Bernardino/Riverside Counties for all subjects (regardless of the age at measurement), and for only those subjects with TSH measurements collected at ≥ 18 hours of age reported by Kelsh *et al.* (2003) were 1.24 (95% CI, 0.89-1.68) and 0.69 (95% CI, 0.27-1.45), respectively. The prevalence ratio for PCH standardized by ethnicity, sex, birth weight, and birth year for Redlands compared to San Bernardino/Riverside Counties was 0.45 (95% CI, 0.06-1.64). The researchers found that Hispanic ethnicity, low and high birth weight, and female sex were risk factors for PCH.

Kelsh *et al.* (2003) did not calculate the odds ratio for having a low T4 (typically defined in this study as a T4 value below 9.0 µg/dL or part of the lowest 5% of the remaining daily tray samples), although this can be estimated using the data in Table 3 of their study. As discussed above, T4 was measured in all newborns, but TSH was only measured if T4 levels were low. Thus, the number of subjects who had "TSH levels screened" represents the number of neonates with low T4 levels. The odds ratio for having a low T4 in Redlands compared to San Bernardino/Riverside Counties was 1.18 (95% CI, 1.13-1.24; $p < 0.0001$). The data used in this calculation is shown in Table 22. This odds ratio is unadjusted. However, it is unlikely that adjusting for age at collection, ethnicity, sex, birth weight, or birth year would have any major impact on this odds ratio since adjusting for these factors had little impact on the TSH odds ratios provided by the authors.

Table 22. Estimated Odds Ratio Calculation for Low T4 in Redlands and in San Bernardino and Riverside Counties Using Data Provided in Kelsh *et al.*, 2003.

Community	Low T4	Normal T4	Total
Redlands	2,081	13,267	15,348
San Bernardino/Riverside	81,401	614,566	695,967
Total	83,482	627,833	711,315

Odds ratio = (2,081/13,267) / (81,401/614,566) = 1.18 (95% CI, 1.13–1.24)

Kelsh *et al.* (2003) also did not report specific results for neonates who had serum TSH measurements collected *before* 18 hours of age. However, data provided in the tables of Kelsh *et al.* (2003) can be used to estimate the odds ratio for having a high TSH level in subjects who had their TSH levels measured during this time. This odds ratio, comparing Redlands to all of San Bernardino/Riverside Counties, was 1.57 (95% CI, 1.14-2.16; $p < 0.0001$). The data used in these calculations are shown in Table 23.

The major strength of the Kelsh *et al.* (2003) study is its large sample size. However, it is limited by the small number of cases of PCH in Redlands, and like most other ecological studies, it was limited by the lack of detailed information on individual exposure (discussed below).

Table 23. Estimated Odds Ratio Calculation for a High Neonatal TSH Level in Subjects with Blood Collected < 18 Hours of Birth Using Data Provided in Kelsh *et al.*, 2003

	TSH Levels		
Area (Perchlorate)	**Elevated[a]**	**Not Elevated**	**Totals**
Redlands (High)	38	4,808	4,846
San Bernardino & Riverside (Low)	1,175	232,990	234,165
Totals	1,213	237,798	239,011

[a]Definitions of "elevated" changed by year, and were between ≥15 and ≥25 µU/mL

Odds ratio = (38/4,808) / (1,175/232,990) = 1.57 (95% CI, 1.14-2.16)

Crump *et al.*, 2000. These investigators studied 162 school-age children (ages 6-8 years old) and 9,784 newborns in three cities in northern Chile that had different concentrations of perchlorate in their drinking water: Taltal (perchlorate concentration, 100 to 120 µg/L), Chañaral (5-7 µg/L), and Antofagasta (non-detectable: <4 µg/L). Approximately 25 separate water sources were sampled in each city. Water samples were taken from water faucets at participating schools, homes of students, and public buildings located near the schools.
The unadjusted mean levels of TSH, T4, fT4, and T3 of the school-age children were very similar across the three cities. Among all the school-age children, there was a small, non-significant increased risk of goiter in Chañaral (26.5 percent) and Taltal (23.3 percent) compared with Antofagasta (17 percent), although this was not seen in analyses confined to life-long residents. The reason for the high prevalence of goiter in the unexposed city of Antofagasta is unknown.

Overall, neonatal TSH levels were similar across the three cities. Adjusted for sex and age, linear regression comparisons of the logarithm (log) of TSH of the newborns by city showed that average logTSH in Taltal was significantly lower than the averages of the other two cities. However, as shown in Table 8 of the Crump *et al.* (2000) paper, TSH levels in those neonates with TSH measured on day 1-2 after birth were higher in Taltal (4.2 µU/mL ± 1.2) than in Antofagasta (3.2 µU/mL ± 3.5) or Chañaral (3.2 µU/mL ± 3.5), although the sample size was small (n = 62).

It should be noted that the iodine levels measured in the schoolchildren in all three study cities were very high. Mean urine iodine levels were 766 µg/L, 614 µg/L, and 756 µg/L for Taltal, Chañaral, and Antofagasta, respectively. These levels are much higher than those in the NHANES III database, where a mean urinary iodine level of 305 µg/L was found for 6-11 year old children in the U.S. The high urinary iodine levels and high prevalence of goiter in this study make it difficult to interpret the relevance of its findings to children in California, where

rates of goiter are much less and moderate iodine deficiency (a potential susceptibility factor) is likely much more common.

Crump *et al*. (2000) found that schoolchildren with lifelong residence in Taltal were five times more likely to have a self-reported family history of thyroid disease than schoolchildren with lifelong residence in Antofagasta. These results were adjusted for age, sex, and urinary iodine (Table 24). Chañaral children had no increased prevalence of self-reported family history of thyroid disease. Families of 19 out of 61 (31 percent) children in Taltal were reported to have some history of thyroid disease. Twelve of these families reported having a single relative (usually a mother or grandmother) with goiter, hypothyroidism, or unspecified thyroid disease; and seven reported having two or more relatives with thyroid disease. The reason why there was evidence of perchlorate-related thyroid effects in older relatives, but not in the children themselves, is unknown. The authors note that the reports on familial history of thyroid issues were not verified and recall bias is possible. They also speculated that this finding might be related to the major changes in average iodine intakes that have occurred in Chile over the last several decades. Iodized salt was introduced to this region in the late 1970's, and average urinary iodine levels in Chile have risen dramatically since that time. For example, according to the International Council for Control of Iodine Deficiency Disorders, average urinary iodine levels in Chile rose from 109 µg/g creatinine in 1982 to 1,191 µg/g creatinine in 2001 (ICCIDD, 2009). It is possible that the elevated odds ratio for a family history of thyroid disease reflects effects that occurred several decades ago when intakes of iodine were low and this low iodine caused some people to be especially susceptible to perchlorate. It is also possible now that iodine levels are much higher, these high levels are protective, and the children and other members of this community are now much less susceptible to perchlorate.

Table 24. Odds Ratios for the Association between Self-Reported Family History of Thyroid Disease[a] among Schoolchildren and City of Residence[b] (Crump *et al*., 2000)

	Schoolchildren with less than lifelong residence (n=162)		Schoolchildren with lifelong residence (n=127)	
City	**Odds ratio**	**95% CI**	**Odds ratio**	**95% CI**
Antofagasta	1.00	-	1.00	-
Chañaral	0.89	0.25-3.19	1.04	0.21-5.09
Taltal	3.35	1.19-9.38	4.97	1.29-19.17

[a]Direct relative (parent, sibling, grandparent, great-grandparent, aunt, uncle, or cousin) with history of goiter, hypothyroidism, or subtotal thyroidectomy.
[b]Adjusted for age, sex, and urinary iodine; excluded one child with autoimmune hypothyroidism.

Assuming the level of perchlorate contamination of the city of Taltal has not changed significantly in the last few decades, a LOAEL of 100 µg/L for familial

thyroid problems can be identified from Crump *et al.* (2000). Applying the default values of 2 L/day for drinking water consumption and 70 kg for an adult body weight, the LOAEL is equivalent to an intake of 3 µg/kg-day from drinking water alone.

Lamm and Doemland, 1999. These authors identified six counties in California (Los Angeles, Orange, Riverside, Sacramento, San Bernardino, and San Diego) and one county in Nevada (Clark) that have had detectable levels of perchlorate (4 to 16 µg/L) in at least some of their drinking water sources. They then compared the rates of primary congenital hypothyroidism (PCH) in these seven counties with overall state rates. All infants were screened by their serum T4 levels, and those with a low T4 (i.e., less than the 10th percentile) were further screened for high TSH levels. An infant was considered to be potentially congenitally hypothyroid if the serum TSH was $\geq$ 25 µU/mL. Infants with these high TSH values were then evaluated by a physician to confirm whether or not they had PCH.

County- and ethnicity-specific data for the two states were obtained for the years 1996 and 1997. Within the seven counties, nearly 700,000 newborns were screened. In all, 249 cases of PCH were identified, where 243 were expected based on the state incidence rate, for an overall risk ratio of 1.0 (95% CI, 0.9-1.2). The risk ratios for the individual counties ranged between 0.6 and 1.1. Out of the 36,016 newborns screened in Clark County (Nevada) between 1996 and 1997, seven cases were observed and 8.3 cases were expected. The risk ratio was 0.8 (95% CI, 0.34-1.74). Based on these results, Lamm and Doemland (1999) concluded that the study did not indicate an increase in the incidence of PCH in those counties with detectable perchlorate levels. Results were not adjusted for several variables related to thyroid hormone levels such as age, gender, or iodine intake, although there is no evidence these factors were related to perchlorate exposure and caused important confounding. Perhaps more importantly, although Clark County of Nevada obtained nearly all of its drinking water from Lake Mead, which is known to be contaminated with perchlorate, the six California counties obtained their drinking water from multiple sources, many of which were not contaminated with perchlorate. Because of this, there was likely significant misclassification of exposure for the California counties. Misclassification could also occur if there were errors in the county to which subjects were assigned, although there is no evidence that this would result in major bias, and bias from this source seems unlikely given the very large size of most of the exposed counties. Importantly, errors in misclassifying exposure would most likely be non-differential and most likely cause bias towards the null. Finally, PCH is a very serious disease, usually requiring treatment with thyroid hormone, and it is generally associated with large increases in TSH. As discussed in subsequent sections, much smaller changes in thyroid hormone levels may also be associated with significant health outcomes, and these more subtle effects would probably be missed in a study that solely focused on physician-diagnosed cases of PCH.

Li *et al.*, 2000a. In a related study, Li *et al.* (2000a) compared serum T4 levels of newborns (collected 1 to 4 days after birth) from the city of Las Vegas, Clark County, Nevada, which has perchlorate in its drinking water, to those from the city of Reno, Nevada, which does not (detection limit, 4 µg/L). A total of 17,308 newborns from Las Vegas and 5,882 newborns from Reno born from April 1998 through June 1999 were included in the study. During the study period, monthly drinking water perchlorate levels for Las Vegas ranged from non-detectable to 15 µg/L. Perchlorate was not detected in the Las Vegas water supply in 8 of the 15 months covered by the study, which the authors suggest may be due to the changing conditions of the water supply to this city. Separate analyses were done to evaluate births in the seven months when perchlorate was detected.

Overall, Li *et al.* (2000a) reported no differences in mean T4 levels (approximately 17 µg/dL) between the two cities ($p = 0.41$), including analyses involving those months where perchlorate was detectable in Las Vegas drinking water (shown in their Figure 1, no p-value given). Specific analyses stratified by age at the time T4 was measured were not presented in detail but are shown in Figure 3 of their paper. Based on this figure it appears that among infants who had their T4 levels collected on day one after birth, the mean T4 level in Las Vegas was about 4 µg/dL (about 22 percent) lower than the mean T4 in Reno.

Li *et al.* (2000a) used the monthly perchlorate measurements in Las Vegas drinking water to estimate the cumulative perchlorate exposure for each newborn during the first three months of pregnancy and for all nine months of pregnancy. Cumulative exposures in Las Vegas ranged from 9 ppb-months to 83 ppb-months; the Reno newborns during this period were presumed to have had no drinking water-related prenatal exposure. In linear regression analyses involving T4 levels collected on all days after birth (not just day one), no association was found between cumulative perchlorate exposure and mean neonatal T4 levels (regression coefficient (β) = -0.0003; $R^2 = 0.002$). Exposure assessment in this study was ecologic and information on whether or not the mothers or infants consumed water from public supplies, or how much they consumed is unknown. As discussed below, this would most likely cause bias towards finding no effect. Misclassification of true long-term thyroid hormone status could also have caused some bias, but again, this would most likely be non-differential and thus most likely cause bias toward finding no effect (also discussed below).

Li *et al.*, 2000b. Li *et al.* (2000b) studied neonatal blood TSH levels sampled between December 1998 and October 1999 in Las Vegas (up to 15 ppb perchlorate in drinking water) and Reno (perchlorate below the detection level of 4 ppb). Serum TSH levels were measured in all neonates who had T4 measurements below the 10^{th} percentile in each daily batch of T4 samples (measured in the first 30 days of life). TSH measurements collected on the first day after birth were excluded. (As discussed above, associations between maternal perchlorate exposures and neonatal thyroid hormone levels are probably best evaluated using TSH measurements taken within the first 24 hours after birth.) In addition, only neonates with birth weights of 2.5 – 4.5 kg were

included. The authors found that neonatal TSH levels were not significantly different between Reno and Las Vegas. Mean TSH values in Las Vegas and Reno were 11.5 µIU/mL (± 1.3) and 12.5 µIU/mL (± 1.3), respectively. The TSH regression coefficient adjusted for age and sex comparing Las Vegas to Reno was -0.0004 (95% CI, -0.0241– 0.0233; p=0.973). Several factors could have caused at least some bias towards finding no effect, including the lack of control of birth weight and ethnic origin, the use of broad categories to control for age at TSH collection (2-7 and 8-30 days), the small sample size, and perhaps most importantly, misclassification of exposure and effect and the exclusion of subjects who had TSH measurements at age < 24 hours.

Brechner *et al.*, 2000. This study identified an association between low-level perchlorate exposure in maternal drinking water and serum TSH levels in newborns. As in the studies discussed above, T4 was measured in all newborns, but TSH was only measured in newborns who had low T4 levels. The investigators compared serum TSH levels in newborns from Yuma, a city that obtains its public drinking water entirely from the Colorado River below Lake Mead, with TSH levels in newborns from Flagstaff, a city that obtains none of its public drinking water from the Colorado River below Lake Mead. Although Lake Mead was known to have perchlorate contamination, no useful water monitoring data were available for Yuma and Flagstaff during the study period (between 1994 and 1997) because the detection limit of perchlorate in water was 400 ppb during that time. In March 1997, the detection limit of perchlorate was improved to approximately 4 ppb. In August 1999, U.S. EPA reported that perchlorate levels in Yuma were about 6 ppb in both raw water and finished drinking water (Brechner *et al.,* 2000).

In unadjusted analyses, Brechner *et al.* (2000) found that median newborn TSH levels in Yuma were significantly higher than in Flagstaff (19.9 vs. 13.4 mU/L). The odds ratio for having a low T4 (and thus being screened for TSH) were not presented by the authors but can be estimated using the data they present in Figure 1 of their study. This odds ratio, comparing Yuma to Flagstaff, was elevated (1.19; 95% CI, 1.07-1.33; p = 0.006). The data used to estimate this odds ratio are shown in Table 25. It should be noted that this odds ratio is not adjusted for age or ethnicity. Four cases of congenital hypothyroidism were reported in Yuma but none in Flagstaff. Because of a normal surge in TSH that occurs soon after birth, a major factor influencing newborn TSH levels is the time (after birth) at which the TSH blood samples are collected. This time was significantly earlier in Yuma than in Flagstaff, and this may have caused some of the increase in TSH levels seen in Yuma compared to Flagstaff. However, according to the authors, the difference in mean TSH levels between Yuma and Flagstaff remained after adjusting for age in days at measurement, gender, and race/ethnicity (p = 0.009) (Brechner *et al.*, 2001). Although the effect size of the adjusted results was not reported, median TSH levels in the two cities stratified by age at measurement are presented. Using the data provided in Table 2 of their article, it can be seen that median TSH levels are greater in Yuma than in Flagstaff on most days of age, with the greatest difference seen on days 0-2 of

age (shown in Table 26). The interpretation of this study is complicated by the fact that TSH levels were only measured in samples with low T4 measurements (discussed below). In addition, this study did not adjust for birth weight or gestational age. The difference in altitude between the two cities has also been cited as a possible bias but it is not clear that this potential confounder would be strong enough to cause the results observed. In fact, several studies suggest the opposite: that high altitudes actually decrease thyroxine levels and have little to no effect on TSH levels (Kotchen *et al.,* 1973; Sawhney and Malhotra, 1991; Richalet *et al.,* 2010).

Table 25. Estimated Odds Ratio for Having Low T4 Using Data Provided in Brechner *et al.*, 2000.

	Low T4		
	Yes	**No**	**Total**
Yuma	1,291	6,308	7,599
Flagstaff	519	3,020	3,539

Odds ratio = (1,291/6,308) / (519/3,020) = 1.19 (95% CI, 1.07-1.33)

Table 26. Median TSH Levels in Yuma and Flagstaff Stratified by Day of Blood Collection (Brechner *et al.*, 2000)

Flagstaff				Yuma			
Days	**N**	**%**	**TSH**	**N**	**%**	**TSH**	**Difference[a]**
0	14	3.2%	24.0	121	11.0%	30.4	6.4
1	122	27.5%	22.0	531	48.3%	25.2	3.2

[a]Median TSH in Yuma minus median TSH in Flagstaff.

Buffler *et al.*, 2006. This study was an ecologic analysis comparing neonatal TSH levels in California communities with perchlorate concentrations above 5 µg/L to those in communities with no known drinking water perchlorate measurements above 5 µg/L. Perchlorate levels in community water sources were obtained for the years 1997 and 1998 from the California Drinking Water Program and used to estimate weighted average perchlorate concentrations in community water. TSH levels among 342,257 California newborns screened in 1998 were obtained from the California Department of Health Services (now the California Department of Public Health). The major outcomes assessed in this study were primary congenital hypothyroidism (PCH) and the elevations in TSH typically used to screen for this disorder (i.e., a TSH > 25 µU/mL collected more

than 24 hours after birth). As discussed for the Kelsh *et al.* (2003) study above, PCH was defined as a TSH level > 25 µU/mL and a physician's confirmatory diagnosis. Subjects who were screened before 24 hours of age were excluded from the analyses by the authors because the normal physiologic post-natal surge of TSH that occurs during this period can increase the rate of false positives when screening for PCH.

Overall, Buffler *et al.* (2006) reported an adjusted odds ratio for having TSH > 25 µU/mL of 0.73 (95% CI, 0.40-1.23) comparing the high to low perchlorate communities. The corresponding odds ratio for PCH was 0.71 (95% CI, 0.40-1.19).

As discussed above, although TSH measurements collected within the first 24 hours of birth may not be the most appropriate for screening for PCH, levels collected during this time may be the most relevant for assessing associations between maternal drinking water perchlorate concentrations and changes in neonatal thyroid hormone levels that are less severe than those typically seen with PCH. The odds ratio for all subjects (those with TSH measured < 24 hours of age combined with those with TSH measurements at ≥ 24 hours of age) were not reported by the authors but can be estimated from the data given in Table 1 of Buffler *et al.* (2006). The unadjusted OR for high TSH comparing communities with perchlorate concentrations above and below 5 µg/L in all subjects regardless of the age of measurement was 1.59 (95% CI, 1.33-1.91). The data used in these calculations are presented in Table 27. Again, this odds ratio was not reported by the study authors, and it is an unadjusted odds ratio.

Table 27. Data for Estimated Unadjusted Odds Ratio Calculations for All Subjects in Buffler *et al.* (2006)

	TSH levels		
Perchlorate	**Elevated**	**Normal**	**Totals**
> 5 µg/L	147	50,179	50,326
< 5 µg/L	537	291,394	291,931
Totals	684	341,573	342,257

Odds ratio = (147/50,179) / (537/291,394) = 1.59 (95% CI, 1.33-1.91)

Given the normal TSH surge that occurs in the first 24 hours after birth, OEHHA evaluated the possibility that this elevated odds ratio could be due to earlier TSH testing in the communities with perchlorate > 5 µg/L. An estimate of the percentage of neonates with TSH measurements before and after 24 hours can be obtained by subtracting the number of TSH levels measured at ≥ 24 hours (given in Buffler *et al.*, 2006, Table 4) from the total number of TSH measurements (at any age) (given in Buffler *et al.*, 2006, Table 1). These data are shown in Table 28 below. (These are estimates since Buffler *et al.*, 2006, Table 1 appears to include all subjects whereas Buffler *et al.*, 2006, Table 4

appears to only include subjects who have all of the data on the co-variates used in their adjusted analyses.)

Table 28. Subjects with TSH Measurements before and after 24 Hours of Birth (Buffler *et al.*, 2006)

	Perchlorate	
	≤ 5 µg/L	> 5 µg/L
Total subjects (Table 1)	291,931	50,326
High TSH (Table 1)	537	147
Total > 24 hours (Table 4)	185,528	29,114
Percent	63.6%	57.9%
High TSH (Table 3)	124	15
Percent with high TSH	0.067%	0.052%
Total < 24 hours (calculated)	106,403	21,212
Percent	36.4%	42.1%
High TSH (Table 3)	413	132
Percent with high TSH	0.39%	0.62%

Based on these numbers, the percentage of all neonates with TSH measurements collected within the first 24 hours of birth was greater in the high perchlorate communities than in the low perchlorate communities (42.1 versus 36.4 percent). Importantly though, when analyses are confined to only those subjects with TSH measurements collected at < 24 hours of age, the unadjusted odds ratio for high TSH comparing communities with and without perchlorate > 5 µg/L remained elevated (OR = 1.60; 95% CI, 1.32-1.94). If age at measurement were an important confounder, the expected odds ratio would be near 1.0 after stratifying by age. It is unlikely that the entire 60 percent increase in risk would go away with an even more detailed stratification or adjustment by age at sample collection.

Steinmaus *et al.*, 2010. Individual data were obtained from the Buffler *et al.* (2006) study, and analysis of these confirmed the elevated odds ratios discussed above. For example, the odds ratio for TSH > 25 µU/mL within the first 24 hours of birth was 1.53 ($p < 0.0001$; 95% CI, 1.24-1.89). For TSH levels measured more than 24 hours after birth, the odds ratio for TSH > 25 µU/mL was similar to that reported in Buffler *et al.* (2006). However, a TSH level of 25 µU/mL was the 99.99th percentile of all TSH levels in this age stratum and there were very few exposed cases (n = 13). Because significant neurologic effects have been seen with smaller changes in thyroid hormones (Pop *et al.*, 1999, 2003; Haddow *et al.*, 1999; Klein *et al.*, 2001; Kooistra *et al.*, 2006; Vermiglio *et al.*, 2004), lower TSH cut-off points were also used to define "high" TSH in this paper. When this was done, elevated odds ratios for high TSH were seen both in infants in whom TSH measurements were collected before 24 hours of age and in infants in whom TSH measurements were collected after 24 hours of age. For example, the odds

ratio for having a TSH level above the 95th percentile in samples collected after 24 hours of age comparing perchlorate exposed and unexposed communities was 1.27 ($p < 0.0001$; 95% CI, 1.22-1.33). This study only evaluated TSH levels and it is currently unknown whether the effects seen here cause actual impacts on health and development. These analyses adjusted for age of sample collection, gender, mother's age, per capita income, race/ethnicity, birth weight, and feeding type (breast milk vs. formula), none of which had substantial effects on results. For example, the adjusted and unadjusted ORs for having a TSH level of 25 µU/mL or greater for collection ages less than 24 hours were 1.53 and 1.52, respectively.

The authors of the Steinmaus *et al.* (2010) paper considered analyzing TSH concentrations and community perchlorate concentrations as continuous variables. But, because of the extensively overlapping and continually changing water sources in many parts of California, assigning a single perchlorate concentration to each individual would have introduced considerable misclassification. This would have introduced particularly strong bias in those subjects in the upper ranges of community perchlorate concentration. Instead, communities (and the subjects who lived in those communities) were divided into two groups based on whether or not it was likely the sources of their residential drinking water had perchlorate concentrations greater or less than 5 ppb. Some exposure misclassification was still likely with this type of categorization. However, since the misclassification was most likely non-differential, the bias would likely be in the direction of the null, not in the direction of finding false positive associations.

Li *et al.*, 2001. This study was an ecologic analysis of various thyroid diseases comparing two counties in Nevada: Clark County, where average water perchlorate levels of around 0-14 ppb were reported, and Washoe County which has not had detectable levels of perchlorate in its major drinking water supplies. The largest city in Washoe County is Reno and the largest city in Clark County is Las Vegas. Relative risks for 6 of the 8 diseases assessed comparing Clark County to Washoe County were above 1.0 (although none were statistically significant) including goiter (RR = 1.24), nodular goiter (RR =1.45), thyroiditis (RR=1.69), and other thyroid conditions (RR=1.89). Relative risks for congenital and acquired hypothyroidism were 0.60 and 1.01 respectively. Disease rates were based on Medicaid records which could be a very insensitive marker of the true rates of these diseases since only a fraction of the people in these counties are on Medicaid rolls.

Chang *et al.*, 2003. In a similar study comparing Clark County (known to have elevated perchlorate levels in its drinking water) to the rest of Nevada, no differences were seen in the rates of pediatric neurobehavioral diseases including autism and attention deficit-hyperactivity disorder (ADHD) assessed using Medicaid records. As stated by the authors, "Perchlorate levels in drinking water were measured in Nevada waters following the 1997 detection of perchlorate in the Lower Colorado River with the newly refined perchlorate

assay. The only public water system found to contain perchlorate was that of the Southern Nevada Water Authority (SNWA) that obtained its water from Las Vegas Bay and distributed it to about 96% of Clark County, including the city of Las Vegas. Perchlorate has not been detected in the public water supply of Reno, of Washoe County, or elsewhere in the state of Nevada. The perchlorate content of the raw and finished waters of SNWA have been measured at least monthly, and at times weekly, since July 1997. Perchlorate levels in 149 finished water samples taken between July 1997 and May 2002 had a mean of 10.9 ppb (SD ± 3.9; median = 10.5 ppb; range = nondetect to 23.8 ppb)." Information on the frequency of neurobehavioral diseases in Nevada youths under 18 years old came from the service records of the Nevada Medicaid program for the years 1996–2000. Patients were defined as those under age 18 who were diagnosed with or treated for either ADHD (ICD9 314) or autism (ICD9 299). The "disease incidence" in Clark County and the rest of Nevada was defined as the average annual number of new cases in Medicaid youths seen or treated in each area divided by the number of Medicaid-eligible youths in that area, in the midpoint of 1998. These unadjusted "disease incidences" were then compared, although the results of formal statistical significance testing are not provided. As discussed in many of the other studies reviewed in this section, and reviewed below, results might have been affected by exposure and outcome misclassification or confounding, although too few data are provided to quantitatively evaluate the extent of these issues for this study. Also, no difference was seen in comparisons of 4th grade performance results, although the methods used in this study to assess both exposure and outcome are likely too inaccurate to identify subtle or even moderate effects.

Tèllez Tèllez *et al.*, 2005. Neonatal and maternal thyroid function was assessed in subjects from the same three cities in northern Chile used in Crump *et al.* (2000). These cities (and their mean perchlorate levels in drinking water) were Taltal (100-120 µg/L), Chañaral (5-7 µg/L), and Antofagasta (non-detectable: <4 µg/L). No clear difference was seen in maternal thyroid hormone levels between the three cities (discussed in a subsequent section). In addition, no differences were seen across cities in mean neonatal cord blood fT4 or TSH. Interestingly, 72.7 percent of the births in the high exposure city were males (compared to 49 percent in the low exposure city), and 57 percent of the births from the high exposure city were done by cesarean section (compared to 39 percent in the low exposure city). The reasons for the unusually high proportion of males and the unusually high rate of cesarean-sections in Taltal are unknown.

Mean concentrations of perchlorate in breast milk were similar in the high and low exposure cities (95.6 µg/L versus 81.6 µg/L), although these were highly variable within a city and the median levels were markedly different across cities (< 4 in Antofagasta and 104 µg/L in Taltal). No association was seen between breast milk iodine and perchlorate concentrations. Mean urinary iodine levels in the women were greater than 300 µg/L in all three cities, suggesting that very few women had low iodine intakes. As discussed below, relatively high iodine intakes may help prevent the thyroidal effects of perchlorate. The mean number

of cigarettes smoked per week (0.52 for the 62 women in Taltal) suggested that few if any women were moderate or heavy smokers. In addition, differences in urinary levels of perchlorate were not as great as might be expected based on the perchlorate concentrations reported for the drinking water of each city. For example, maternal urine perchlorate concentrations measured during the post-partum visit for the low, medium, and high exposure cities were 22.3, 17.5, and 49.1 µg/L, respectively, although these measurements were only done in a fraction of the women in the study. A graphical display of the urinary perchlorate levels from all three cities shows a marked overlap across cities. Part of this may have been due to the fact that a large percentage of the women (45 percent) from the high exposure city of Taltal went to the low exposure city of Antofagasta to give birth. Taltal (population about 10,000) is fairly remote and is about 200 miles away from the much larger city of Antofagasta (population about 250,000). Part of it may have been due to exposure from foods or some other unknown source in Antofagasta. Regardless of the cause, the lack of a large contrast in exposure between the subjects from each of the cities probably decreased the likelihood that true associations, if present, could be found.

Amatai *et al.*, 2007. T4 values were measured in newborns in the neighboring cities of Ramat Hasharon and Hertzlia, Israel, whose mothers resided in areas where drinking water had perchlorate concentrations that were very high (340 µg/L, n = 97), high (42-94 µg/L, n = 216), and low (< 3 µg/L, n = 843). The high perchlorate concentrations were found in wells near a military plant. Heel-stick T4 values were measured in all newborns in these communities as part of the national screening program, and were done at 36-48 hours after birth in >90 percent of all newborns. Mothers also completed a questionnaire asking whether they drank tap water, filtered water, or bottled water during their pregnancy.

The mean T4 values in the very high, high, and low perchlorate areas (in µg/dL) were 13.93 (± 3.8), 13.91 (± 3.4), and 13.98 (± 3.5), showing no differences between the exposure areas. It is unclear if these means were adjusted for other factors associated with neonatal T4 levels including gender or the age of the child when the heel stick was taken. No association was seen with neonatal T4 and maternal age, birth weight, gestational age, or sex. No difference was seen in mean T4 values in the analysis confined to only the children of exposed women who reportedly drank tap water during pregnancy, although this included less than 30 percent (n = 93) of the women from the very high and high exposure areas.

Serum perchlorate levels were reported in this study on a small number of people who lived in the study areas and who were proxy donors (i.e., blood bank donors who were not involved in the actual study). Mean serum perchlorate levels (in µg/L) in the very high, high, and low perchlorate areas in these subjects were 5.99 (± 3.89, n = 4), 1.19 (± 1.37, n = 19), and 0.44 (± 0.55, n =14). As seen in Figure 3 of this paper, and in the reported standard deviations, there was considerable overlap in serum perchlorate among the three exposure categories. Serum iodine levels were also measured in the proxy donors. Serum iodine

levels were higher in proxy subjects from the very high/high exposure areas compared to the low exposure area (3.10 µg/L ± 1.25 versus 2.24 µg/L ± 0.85; p = 0.031).

The strengths of this study are its collection of at least some individual data on exposure (i.e., the source of drinking water during pregnancy) and the presumably large contrast in perchlorate exposure. Urinary perchlorate levels would have likely provided a better indication of true exposure but were not measured. Other weaknesses are the lack of information on adjustments for potential confounders, the lack of individual data on smoking and iodine, and the relatively small number of women from the exposed areas who drank tap water during pregnancy. In addition, the authors reported that >90 percent of infants in these areas had their blood sampling at 36-48 hours after birth, suggesting that very few (probably < 4) of the highly exposed study infants had thyroid hormone measurements within the first 24 hours of birth. As discussed above, since the half-life of perchlorate and thyroid hormones is relatively short, this may have limited the ability of this study to find an association between maternal perchlorate exposure during pregnancy and neonatal thyroid hormone levels.

Blount *et al.*, 2009. Perchlorate, nitrate, thiocyanate, and iodine were measured in maternal urine (n=34), amniotic fluid (n=130), cord blood (n=126), and maternal serum (n=132) in mother-offspring pairs from New Jersey. Only subjects scheduled for elective cesarean section were included, and maternal blood and urine were collected within one hour before the surgery. Correlations between the various exposure parameters, as well as associations between perchlorate concentrations in cord blood and birth weight, length, and head circumference, were assessed. Correlations between perchlorate concentrations in maternal urine and concentrations in maternal blood and cord blood were low (-0.10 and 0.20, respectively). Clear associations between concentrations of cord blood perchlorate and birth weight, length, and head circumference were not seen. Because the sample size was relatively small, only very large changes in birth weight, head circumference, and birth length would be detectable with sufficient statistical power. In addition, these outcomes are indicative of effects that are likely much more severe than would be expected from the fairly low perchlorate exposures measured in this study (median urine perchlorate = 2.76 ug/L; 90^{th} percentile = 4.35 ug/L). Finally, urine, rather than blood, is the most common metric used to assess perchlorate exposure, but urine perchlorate was only measured in 34 pregnant women and analyses of associations between maternal urinary perchlorate and fetal birth weight, head circumference, and birth length were not presented.

Cao *et al.*, 2010. Urinary concentrations of perchlorate, nitrate, iodine, thiocyanate, T4 and TSH were measured in 92 full term infants from Pennsylvania. In analyses adjusted for age, sex, and body mass index, increasing urinary perchlorate concentrations were associated with increasing urinary TSH concentrations, but only in children with low urinary iodine. The adjusted regression coefficient between the logarithm of urinary perchlorate and

logarithm of urinary TSH was 0.10 (95% CI, 0.01- 0.19) in children with urinary iodine levels < 100 µg/L and –0.04 (95% CI, –0.12-0.04) in children with higher iodine levels. Increasing urinary concentrations of perchlorate, nitrate, and thiocyanate were also associated with higher urinary T4. Both urinary levels of thyroid hormones and urinary levels of perchlorate (and other analytes) were "adjusted" for urine dilution by dividing their values by the subject's urinary creatinine concentrations. The use of urinary creatinine on both sides of the mixed model analyses (i.e., as part of the dependent variable and as part of the independent variable) may have led to the positive correlations identified in this study, making these results difficult to interpret.

Summary of Studies of Perchlorate and Infant Thyroid Hormone Levels

Table 29 summarizes data from the most relevant studies of perchlorate exposure and newborn thyroid hormone levels. In several studies, the authors did not specifically present results for the early newborn period, but provided data that OEHHA used to perform its own evaluation of possible associations for this period. These are clearly marked in Table 29 under the heading "Source of data and results." It should be noted that the data points calculated by OEHHA are not based on the original study authors' conclusions and most represent unadjusted estimates. Any conclusions drawn from this table should be interpreted in light of these facts. Table 30 lists the studies that were excluded from Table 29, with reasons for their exclusion. The Li *et al.* (2000) and Amatai *et al.* (2007) studies are excluded from this table because they did not include a substantial portion of subjects who had thyroid hormone levels measured within the first 24-36 hours after birth. As discussed above, this period is likely the most relevant time frame for assessing the effects related to maternal exposures during pregnancy. Tèllez Tèllez *et al.* (2005) is excluded from the table because 45 percent of the newborns from the exposed city were born in the unexposed city and therefore were probably not exposed at the time of birth. The Tèllez Tèllez *et al.* (2005) study is also inconsistent with the other studies in Table 29 because the very high iodine levels in this population may have protected the infants in this study from the effects of perchlorate and, more importantly, because a large fraction of women from the highly exposed town gave birth in the low exposure city. The Buffler *et al.* (2006) study was not included because it used the same data as Steinmaus *et al.* (2010) but did not focus on newborns.

As seen in Table 29, at least some evidence of an association was seen with perchlorate in each of the five data sources that included information on newborn thyroid hormone levels. Several aspects of these findings provide evidence that they represent real effects. First, despite major differences in study populations, study designs, time periods, funding sources, and research groups, these results are markedly consistent across studies. This type of consistency across different studies is one of the major tenets of causal inference (Hill, 1965; Rothman and Greenland, 1998b). Second, several of these results have very low p-values, which means that they are probably not due to chance. Third, these findings are consistent with the known biologic mechanism of perchlorate. That is, these

results show that perchlorate may decrease T4 and increase TSH, both of which are effects that are in the direction expected based on the known mechanism of action of perchlorate.

Several additional issues potentially affect the interpretation of these results and these are discussed in the following sections.

Ecologic assessment of perchlorate exposure: Most of these studies used average perchlorate concentrations in large community drinking water supplies as a surrogate for exposure to the individuals in that community. In all of these studies, the reported perchlorate concentrations were based on a relatively small number of samples. Average perchlorate concentrations were then assigned to individuals without knowledge of whether or not they drank the tap water, how much they drank, or for how long they drank it. In addition, drinking water is not the only source of perchlorate, and some exposure will come from food. Lack of data on other sources of perchlorate would likely cause further misclassification of the study subjects' true perchlorate exposure. Importantly though, study subjects were classified in terms of their perchlorate exposure independently of their thyroid hormone status. Thus, any misclassification of exposure is likely to be independent of thyroid hormone status (i.e., non-differential). This type of non-differential misclassification of exposure will likely bias results towards the null. That is, if an association truly exists, non-differential exposure misclassification will most likely cause the magnitude of the observed association to be less than the magnitude of the true association. It will not likely cause a false association or strengthen an association that is truly weak. There are some rare exceptions to this rule, but these exceptions are not likely applicable to the studies in Table 29 (Rothman and Greenland, 1998a).

Despite this misclassification bias, which was likely present to some degree in every one of the data sources evaluated, OEHHA found evidence of an association in each of the data sources presented in Table 29. If non-differential misclassification of exposure could somehow be corrected for in these studies, the effects found would likely be even greater than those reported.

Table 29. Information on Maternal Perchlorate Exposure during Pregnancy and Thyroid Hormone Levels in Early Newborns

Location and source of data	Exposed (exposure level in water)	Unexposed	Results: Exposed group compared to the unexposed group		Source of data and results	Adjustments, stratifications or exclusions	Summary notes regarding confounding[a] and other related findings	
			T4	TSH				
California	Redlands (9 ppb)	Rest of San Bernardino & Riverside Counties	No data	OR for high TSH = 1.57 (95% CI, 1.14-2.16; p < 0.0001) (Table 23 and page 63)	Calculated by OEHHA using raw data provided in Kelsh *et al.*, 2003	Unadjusted results	Adjustments for birth weight, ethnicity, sex, birth year, age, and multiple births had little effect on the authors' original results.	OR for low T4 = 1.18 (95% CI, 1.13-1.24; p < 0.0001) for all ages (Table 22 and pages 62-63)
California	Exposed communities (> 5 ppb)	Unexposed communities (< 5 ppb)	No data	OR for high TSH = 1.53 (95% CI, 1.24-1.89; p < 0.0001)	Steinmaus *et al.*, 2010	Age, gender, race/ ethnicity, feeding type, birth weight, outliers, household income.	None of these factors except formula feeding had major impacts on results.	
Arizona	Yuma (4-6 ppb)	Flagstaff	No data	Mean TSH = 27% higher (Table 26 for day 0)	Calculated by OEHHA using data and results provided in Brechner *et al.*, 2000	T4 findings based on unadjusted analyses. TSH findings in analyses stratified by age and race/ethnicity.	In follow-up analyses, TSH remained elevated in the exposed town after entering age, race/ethnicity, and sex into the statistical models.	OR for low T4 = 1.19 (95% CI, 1.05-1.33; p = 0.006) for all ages (Table 25 and pages 67-68)

Table 29 (continued). Information on Maternal Perchlorate Exposure during Pregnancy and Thyroid Hormone Levels in Early Newborns

Nevada	Las Vegas (0-9 ppb)	Reno	Mean T4 ≈ 22% lower	No data	Estimated by OEHHA using the data presented in Figure 3 of Li *et al.*, 2000a	Unadjusted result	In the analyses done by the authors, adjustments for sex, birth weight, and age appear to show no major confounding effect.	
Chile	Taltal (100 ppb)	Antofagasta and Chañaral (0-5 ppb)	No data	Mean TSH ≈ 45% higher	Based on the results presented in Table 8 of Crump *et al.*, 2000	Results stratified by age	Median age greater in Taltal than other cities (6.6 vs. 4.1 days). Correcting for this would increase TSH levels in Taltal.	OR for a family history of thyroid disease in all lifelong residents was 4.97 (95% CI, 1.29-19.17)

[a]Further details on the assessments of confounding are provided in the next section.

Table 30. Excluded Studies

Excluded studies	Reason for exclusion
Tèllez Tèllez *et al.*, 2005	45% of women from the exposed city delivered in the unexposed city.
Li *et al.*, 2000b	TSH measurements collected on first day after birth were excluded.
Amatai *et al.*, 2007	< 10% of newborns had thyroid hormones measured in first 36 hr after birth.
Cao *et al.*, 2010	Adjustments for urinary creatinine could have created false associations. No data in neonates.
Buffler *et al.*, 2006	Used the same data as Steinmaus *et al.* (2010), but did not focus on newborns.

Misclassification of thyroid hormone status: The studies discussed above assessed thyroid hormone status using a single measurement of thyroid hormone. Thyroid hormone levels can vary in individuals from day to day and within a day. This variability means that a single assessment of serum thyroid hormone concentration could lead to misclassification of true long-term thyroid hormone status in some individuals. Importantly though, any errors in misclassifying outcome are likely to be the same as those associated with misclassifying exposure: non-differential misclassification that will likely bias results to the null. As with exposure misclassification, if these errors could be corrected, the effects reported in the positive studies listed above would likely be even greater than those reported.

Confounding:

a. General concepts

Several general concepts were considered in evaluating confounding in these studies. The first is that a factor must be associated with both the exposure (perchlorate) and the outcome (thyroid hormones) of interest to cause confounding. A factor may be a strong determinant of thyroid hormone levels, but if it is not associated with perchlorate exposure then it is unlikely to cause important confounding (Axelson, 1978). For many of the factors potentially related to thyroid hormone levels such as menopause, premenarche, physical activity, c-reactive protein, thyroid antibodies, thyroid diseases, use of certain medications, and many others there is no evidence or plausible reason to support that they are also associated with perchlorate exposure. As such, there is no evidence or logical reason to believe that they are important confounders in the studies presented in this section.

The second general concept is that in order for a factor to cause important confounding, it not only needs to be associated with the exposure and the outcome of interest, but these associations must be fairly strong (Axelson, 1978). A factor that is only weakly associated with either the exposure or the outcome may still cause some confounding, but the impact of this confounding on the study result will usually be minor and likely unimportant.

An example of this is given below for thiocyanate. In this example, and in the other examples provided in this section, the focus is on those factors which would most likely cause confounding and bias, including those factors commonly referred to in the current perchlorate literature. Here, the potential effect of thiocyanate as a confounder on studies assessing T4 is assessed using the methods presented by Axelson (1978) (Table 31). In this example, the mean serum T4 concentrations for various levels of thiocyanate exposure were obtained using data from NHANES 2001-2. The thiocyanate categories used in this example are the tertiles of thiocyanate in women from NHANES 2001-2 (Steinmaus *et al.,* 2007). These categories were selected because they were the ones in which perchlorate-T4 associations were found to differ in Steinmaus *et al.* (2007). As shown in these analyses (Table 31), mean T4 decreases as thiocyanate increases from the lowest (< 750 µg/L) to the highest tertile (> 1800 µg/L), but this decrease is small. Because the effect of thiocyanate on T4 is small, even if the proportion of women with high thiocyanate levels is twice as high in a study's higher perchlorate-exposed group (e.g., 66.7 percent with high thiocyanate, last row) as in the study's lower perchlorate-exposed group (e.g., 33.3 percent with high thiocyanate, shaded row) this would have only a very small effect (1.4 percent) on the mean difference in T4 between the perchlorate higher and lower exposed groups. This example shows that even if thiocyanate exposure is associated with both thyroid hormone levels and with perchlorate exposure, these associations are likely too weak to cause the effects seen in Table 29. The same is likely true for many other factors such as race, age, sex, obesity, socioeconomic status, nitrate, and iodine. In other words, while it is possible that all of these factors could be associated with both thyroid hormone levels and perchlorate exposure, the magnitude of these associations are, like thiocyanate, probably too weak to cause important confounding. Thus, while they may cause some confounding (e.g., they could change an unadjusted odds ratio of 1.52 to an adjusted odds ratio of 1.53 as in Steinmaus *et al.,* 2010), the magnitude of the confounding effect will likely be too small to affect the overall study conclusions.

Table 31. Analysis of the Potential Magnitude of Confounding by Thiocyanate Using the Methods of Axelson, 1978

Thiocyanate (µg/L)	<750	750-1800	>1800	M_o	Mean Diff	Mean Diff
Mean T4 (µg/dL):	8.632	8.496	8.272	(µg/dL)	(µg/dL)	%
Lower perchlorate exposure	33.3%	33.3%	33.3%	8.47	Ref	Ref
Higher perchlorate exposure	31.7%	33.3%	35.0%	8.46	0.01	0.1%
	26.7%	33.3%	40.0%	8.44	0.02	0.3%
	21.7%	33.3%	45.0%	8.42	0.04	0.5%
	16.7%	33.3%	50.0%	8.41	0.06	0.7%
	0.0%	33.3%	66.7%	8.35	0.12	1.4%

M_o, mean T4 expected in a group of subjects with this distribution of thiocyanate; Mean Diff, mean difference in T4 in the lower perchlorate-exposed group minus the higher perchlorate-exposed groups; Ref, lower perchlorate-exposed reference group

A third general concept of confounding is that factors that are very rare are unlikely to cause significant confounding in large population-based studies. These factors include rare thyroid diseases, certain genetic conditions, and the use of certain medications known to impact thyroid hormone levels.

Fourth, it is important to note that each of the five positive studies listed in Table 29 involved different study populations, different time periods, different study methods, and different research groups. Despite all of these differences, the effects identified across all of these studies were similar and consistent. This consistency decreases the likelihood that confounding is responsible for all of the effects identified. It is possible that the same confounder affected each of these studies. However, some of these studies adjusted or stratified for several of the factors known to be among the most important population-wide determinants of thyroid hormone levels (age, sex, and race) and found these adjustments made very little difference. It is possible that those studies which did adjust or stratify for confounders were not impacted by confounding while those studies or analyses which were unadjusted were affected by confounding. However, there is no evidence or plausible reason to support that this is the case, and again, the consistency of the findings across the different studies argues against this. It is also possible that each of the five studies or analyses in Table 29 was affected by five entirely different confounders. However, it seems highly unlikely that five different confounders would all lead to essentially the same effect in five different studies and in five different study populations. All told, the consistency of the effects seen in the different studies in Table 29, combined with the fact that adjusted results showed essentially no evidence of confounding (see below), argues against the idea that confounding played a major role in these results.

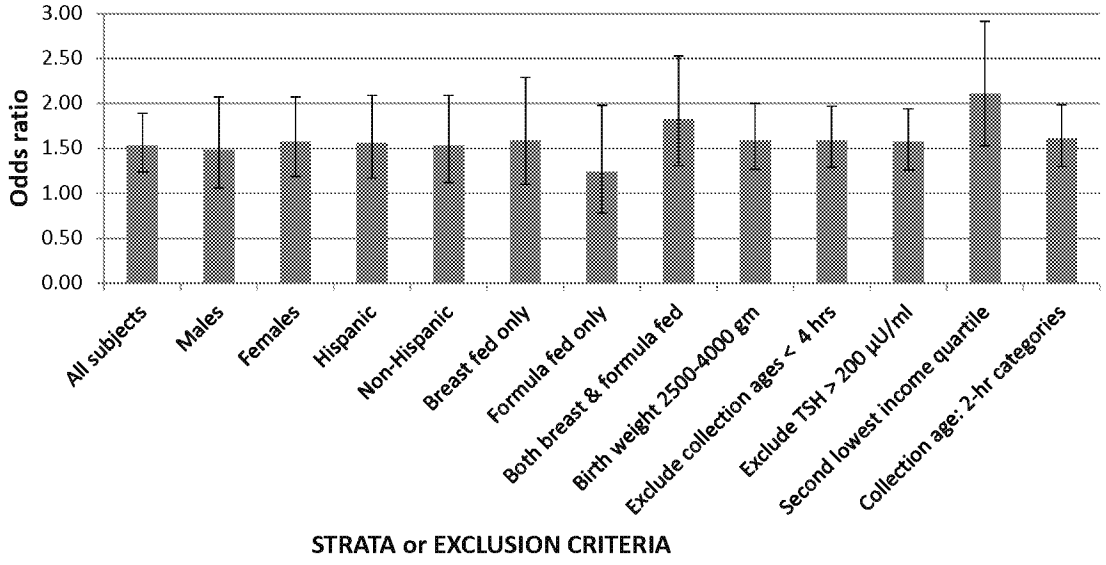
Finally, many of the factors related to thyroid hormone might not cause important confounding for the reasons given above, but they may still act either cumulatively or synergistically with perchlorate to decrease thyroid function. Certain factors such as nitrate and thiocyanate act by the same mechanism as perchlorate, and as discussed in the following sections, some evidence exists that people exposed to one or more of these agents may be particularly susceptible to perchlorate. For example, some perchlorate-thyroxine findings from NHANES suggest that thiocyanate, perchlorate, and low iodine intake could act cumulatively or synergistically (Blount *et al.,* 2006; Steinmaus *et al.* 2007; Steinmaus *et al.,* 2013). Other factors, such as polychlorinated biphenyls (PCBs) or anti-thyroid antibodies likely affect thyroid function by different mechanisms but might also act cumulatively or synergistically with perchlorate to adversely impact thyroid function. Importantly, this type of effect is not confounding, and is usually not evaluated or "controlled" in the same way as confounding. Instead, these types of effects would create groups of people who may be especially susceptible to perchlorate.

b. Evidence for or against confounding in each study

Steinmaus *et al.,* 2010: As discussed above, this study adjusted for many different potential confounding variables including age, gender, race/ethnicity, type of feeding, birth weight, and community average household income, and these had little impact on study results and no impact on study conclusions. For example, in the analysis of whether TSH levels were greater than 25 µU/mL in the first 24 hours after birth, the unadjusted odds ratio for having elevated TSH, comparing perchlorate-exposed and unexposed communities, was 1.52. After adjusting for age, gender, race/ethnicity, type of feeding, birth weight, and community average household income, the odds ratio was 1.53. Thus, the excess odds ratio changed by less than 2% with adjustment. This very small 2 percent change is strong evidence that none of these factors caused major confounding. It also provides evidence that residual confounding from incomplete adjustment of any of these factors is likely to cause effects that are even smaller than 2 percent.

In addition to statistical adjustments, the use of stratified analyses and exclusion criteria are two other ways of evaluating the role of confounding. Figure 8 shows the odds ratios for having a TSH level above 25 µU/mL comparing neonates from perchlorate-exposed and unexposed communities in analyses using a variety of stratification and exclusion criteria. As shown, statistically significant elevated odds ratios are seen in all analyses except the analysis of formula fed infants. The lower odds ratio in formula fed infants is consistent with the exposure misclassification soon after birth discussed on page 60 above. The fact that the elevated odds ratios remained in all the other analyses is evidence that none of these factors had important effects on results, or more importantly, on the conclusion that perchlorate exposure is associated with increased neonatal TSH levels in this dataset.

Figure 8. Odds Ratios for TSH > 25 µU/mL within 24 Hours of Birth Comparing Perchlorate-exposed (> 5 µg/L) and Unexposed (≤ 5 µg/L) Communities in Analyses Stratified by Age, Gender, Race/Ethnicity, Feeding Type, Birth Weight, or TSH Outliers (Steinmaus *et al.*, 2010) [The vertical lines are 95% confidence intervals]



Kelsh *et al.*, 2003: Using the data provided in the tables of this article, OEHHA estimated an odds ratio of 1.18 (95% CI, 1.13-1.24; $p < 0.0001$) for having a low T4 level and an odds ratio of 1.57 (95% CI, 1.14-2.16; $p < 0.0001$) for having an elevated TSH level. While it is possible these elevated odds ratios are due to some unknown confounding, several pieces of evidence argue against this. First, in the analyses done by Kelsh *et al.*, adjustments for birth weight, ethnicity, sex, birth year, age, and multiple births had little impact on the odds ratios they calculated. For example, comparing Redlands (exposed) to the rest of San Bernardino and Riverside Counties (unexposed), the odds ratio for having an elevated TSH level changed from 1.28 to 1.24 after adjustments for all of these factors. This small change suggests that none of these factors had important confounding effects in this study. Therefore, despite the fact that a few of these factors were shown to be related to neonatal TSH levels in this study (e.g., ethnicity and birth weight), they were not different enough between perchlorate-exposed and unexposed areas to cause major confounding. This provides strong evidence that the unadjusted odds ratios calculated by OEHHA are also not due to confounding by these factors since the OEHHA analyses involved the exact same perchlorate-exposed and unexposed areas used in the original authors' own calculations.

A second piece of evidence that the unadjusted odds ratio calculated by OEHHA is not due to confounding is the fact that this unadjusted odds ratio is remarkably close to the adjusted odds ratio in the corresponding analysis in Steinmaus *et al.* (2010). That is, for subjects with TSH collection ages within 18 to 24 hours after birth, the odds ratio for having TSH > 25 µU/mL was 1.57 using unadjusted data

from Kelsh *et al.* (2003) and 1.53 in the Steinmaus *et al.* (2010) adjusted analyses. The similarity of these two odds ratios, combined with the fact that adjustments or stratifications for age, gender, race/ethnicity, feeding type, birth weight, and community household income had little effect on the Steinmaus *et al.* (2010) results provides additional evidence that the elevated unadjusted odds ratio calculated by OEHHA using the Kelsh *et al.* (2003) data is not due to confounding by the factors adjusted for in Steinmaus *et al.* (2010).

Brechner *et al.*, 2000: An odds ratio of 1.18 (95% CI, 1.05-1.33; p=0.006) for decreased T4 and a 27 percent higher TSH level was found comparing perchlorate-exposed Yuma to unexposed Flagstaff. The T4 odds ratio was based on unadjusted data provided in the article while the TSH results were based on analyses stratified by age and race/ethnicity. In a subsequent Letter to the Editor, the authors state that the difference in TSH levels remained higher in Yuma than Flagstaff when sex, age, and race/ethnicity were included in the analysis of variance (p= 0.009), suggesting that these three variables were not strongly related to perchlorate exposure and were not responsible for the relationship between perchlorate exposure and TSH identified in this study. Because these three variables caused little confounding in the analysis by Brechner *et al.* (2000), and because the unadjusted odds ratio of 1.18 was calculated using the exact same perchlorate exposed and unexposed areas (Yuma and Flagstaff, respectively) as defined by the authors of this study, it is unlikely these factors confounded and are responsible for the elevated unadjusted odds ratio of 1.18 calculated by OEHHA. Lamm (2003) suggests that the differences in altitude between the two cities might be responsible for the effect identified. However, Lamm provides no evidence for this, and as discussed above, several studies show that altitude causes effects that are directly opposite to those proposed by Lamm (2003). The likelihood that other potential confounders such as socioeconomic status, iodine, or other environmental chemicals had major effects is discussed below.

Li *et al.*, 2000a: Based on data provided in Figure 3 of this article, newborn T4 levels on day 1 after birth appear to be about 22 percent lower in perchlorate-exposed Las Vegas than in unexposed Reno. On almost all other days after birth except day 1, T4 levels appear to be similar between the two cities. This pattern (effects seen on day 1 after birth but not later) is consistent with the likely impacts of exposure misclassification on maternal perchlorate-neonatal TSH relationships that occurs several days after birth (see pages 59-60). In the authors' analyses, adjustments for gender, birth weight, and age appear to have very little effect on results. For example, in the unadjusted analyses, the difference in mean T4 levels between Las Vegas and Reno was close to zero (mean difference = 0.01; means of 17.11 and 17.12 µg/dL, respectively; p = 0.901). In the adjusted analysis, this difference was also about zero (mean difference = 0.069 µg/dL, p = 0.407). As in the preceding studies, the very small difference between the adjusted and unadjusted analyses provides evidence that confounding had very little impact on these results and that age, birth weight, and

sex were not strongly enough related to both perchlorate exposure or thyroid hormone levels to cause substantial confounding.

Crump *et al.*, 2000: In an unadjusted analysis of TSH measurements collected on days 1-2 after birth, the median TSH level in the high exposure city of Taltal was 45% higher than that in the low exposure city of Antofagasta, although the sample sizes were small. Several factors suggest that this result is not due to confounding. First, TSH measurements were, in general, collected later in the exposed city of Taltal than they were in the unexposed city of Antofagasta. Since TSH levels tend to decrease with time after birth, based on this factor alone, one would expect that TSH levels would be lower in Taltal than Antofagasta. Given this, adjusting for age at the time of TSH collection would most likely increase, not decrease the difference seen between Taltal and Antofagasta. Second, in addition to the TSH findings, this study also reported elevated odds ratios (ORs) for a family history of thyroid disease in Taltal compared to Antofagasta (OR = 3.35, 95% CI, 1.19-9.38 in all subjects and OR = 4.97, 95% CI, 1.29-19.17 in lifelong residents). These odds ratios were adjusted for age, sex, and urinary iodine. The unadjusted odds ratio for a family history of thyroid disease in all subjects, which could be calculated using the data provided in their Table 3, was 2.85 (95% CI, 1.07-7.42). The fact that the unadjusted odds ratio is only a little lower than the adjusted odds ratio (2.85 versus 3.35) suggests that while age, sex, and urinary iodine had some confounding effects, the magnitude of this confounding was not strong enough to mask an association. The fact that age, sex, and urinary iodine did not cause significant confounding in the analysis of family history of thyroid disease provides that these factors are not likely to cause major confounding in the analysis of neonatal TSH levels. The notion that iodine is an unlikely confounder in this study is also supported by the fact that the mean urinary iodine levels reported in children in the two cities is very similar: 75.6 ± 40.4 µg/dL in Antofagasta and 76.6 ±47.4 µg/dL in Taltal. This similarity provides strong evidence that iodine was not related to this study's main metric of perchlorate exposure (city of residence) and thus was not likely a major confounder. Ethnic differences are unlikely to have caused the effects seen since there are no major ethnic differences between these cities. Finally, nitrate levels in these cities are below U.S. recommended levels, so nitrate was an unlikely cause of the positive effects seen.

c. Other data on confounding

In this section we evaluate the likelihood that various individual uncontrolled factors might have caused confounding in the studies discussed above. Since many different things can affect thyroid hormone levels, one could hypothesize that many different things could potentially cause confounding. However, since few are strongly related to perchlorate exposure, few are likely to cause confounding. Because of this, OEHHA chose not to evaluate each of the hundreds of different factors that can affect thyroid hormone levels, but rather chose those factors that seem to be discussed most often in the current literature on perchlorate. These factors include iodine, nitrate, other environmental

chemicals like polychlorinated biphenyls (PCBs), and thyroid antibodies. Other factors such as race/ethnicity and thiocyanate were discussed above. The age of neonatal sample collection is not discussed here since all of the studies in Table 29 either adjusted for or stratified by this variable.

Iodine and nitrate: Data from Blount *et al.* (2006) and Steinmaus *et al.* (2007) suggest that iodine is more likely to be an effect modifier than a confounding variable. In other words, findings from these studies suggest that low iodine intake (and high thiocyanate levels) are more likely to produce additive or synergistic effects on thyroid hormone levels with perchlorate than cause false associations between perchlorate and thyroid hormone levels. In both Blount *et al.* (2006) and Steinmaus *et al.* (2007), adjusting for thiocyanate and nitrate had little effect on the perchlorate-T4 regression coefficient in women with low iodine levels. While some studies suggest that nitrate intake may affect thyroid hormone levels, thyroid volume, or goiter, questions regarding actual intake levels, control for iodine intake, and blinding of outcome assessments raise concern about the validity of their results (Tajtakova *et al.,* 2006; Gatseva *et al.,* 2008). Also, common nitrate exposures in the U.S. may not be high enough to affect thyroid function. In a clinical trial, a nitrate dose of 15 mg/kg-day for 28 days did not decrease thyroidal iodide uptake or impact thyroid hormone levels in 10 healthy volunteers (Hunault *et al.,* 2007). This intake level is 5-20 times, or more, higher than average nitrate intakes reported in several populations in Europe and the U.S. (OEHHA, 2000). These findings suggest that nitrate is an unlikely cause of the effects identified in the positive studies discussed above. Although iodine intake has been shown to affect thyroid hormone levels, these effects may only occur at extreme values of iodine, not at the levels most commonly seen in the U.S. For example, Soldin *et al.* (2005) found little evidence of an association between urinary iodine concentrations and serum levels of T4 or TSH in NHANES. Since the potential for confounding is directly related to the strength with which the potential confounder is associated with the outcome of interest, these findings suggest that iodine is very unlikely to cause significant confounding unless studies are done in areas where a very large fraction of the population has very low iodine intakes (and this low intake is associated with perchlorate exposure).

Other environmental chemicals: Some studies have found associations between certain chemicals such as PCBs and thyroid hormone levels (Chevrier *et al.*, 2007), but these effects are generally small and there is little evidence that the relationship between PCB exposure and perchlorate exposure is strong enough that PCBs are likely to cause important confounding in studies of perchlorate and thyroid hormones. To further evaluate this, correlation coefficients between urinary perchlorate levels and serum PCB levels were calculated using data from NHANES 2001-2 (the same data used in Blount *et al.,* 2006 and Steinmaus *et al.,* 2007). As shown in Table 32 these correlations are very low and therefore too small to cause any significant impacts on the study results reported above.

Table 32. Spearman Correlation Coefficients (R) between Serum PCBs and Urinary Perchlorate, NHANES 2001-2

PCB	R	p-value	N
52	-0.04	0.09	1474
99*	0.04	0.09	2192
101	-0.01	0.64	2217
118	0.06	0.009	2217
153	0.05	0.01	2216
156	0.06	0.005	2206
180	0.05	0.01	2212
183*	0.01	0.38	2216
184	0.04	0.05	2217
194*	0.05	0.02	2191
199*	0.05	0.01	2202

*The congeners with correlation coefficients > 0.10 between the PCBs and neonatal TSH levels in Chevrier *et al.* (2007).

Thyroid autoantibodies: In its recent report on perchlorate, the American Thyroid Association (2006) calls thyroid autoantibodies "an important confounder in thyroid physiology." In order to evaluate the possibility that these might be important confounders, OEHHA used data from NHANES 2007-8 to evaluate the magnitude of the association between thyroid autoantibodies and serum T4 using linear regression analyses adjusted for age and sex. As shown in Table 33, the magnitudes of these relationships were very small suggesting that these antibodies are unlikely to be important confounders in general population-based studies.

Table 33. Age and Sex Adjusted Associations between Total Thyroxine (T4) (µg/dL) and Thyroid Autoantibodies in NHANES 2007-8.

	Coefficient	SE	p-value
Thyroid peroxidase antibody (IU/mL)	-0.000233	0.00121	0.85
Thyroglobulin antibody (IU/mL)	-0.000221	0.000208	0.31

Study size: Several of these studies involved a very large number of study subjects [Kelsh *et al.* (2003), Brechner *et al.* (2000), and Buffler *et al.* (2006)], and the p-values are less than 0.001. These very low p-values provide evidence that the elevated odds ratios identified in these studies are unlikely due to chance. In Brechner *et al.* (2000), although the odds ratio for low T4 was somewhat small (OR = 1.18; 95% CI, 1.05-1.33), the p-value was 0.006, which again, suggests that the excess odds are unlikely due to chance.

A lack of statistical power may have affected some of the smaller studies. If relative risks are expected to be fairly low (e.g., less than 2.0), large sample sizes are needed to detect statistically significant associations. The small sample sizes and relatively low prevalence rates of the outcomes of interest of some studies might have limited their ability to identify true effects.

Subject selection: There is a concern about the way the neonate blood samples were selected for TSH determination in the studies reported by Brechner *et al.* (2000), Kelsh *et al.* (2003), and Li *et al.* (2000b). In these studies, TSH levels were only measured in newborns who had low T4 levels. The TSH findings of these studies are still important, however, because they indicate that the risk of having *both* a low T4 level and a corresponding high TSH level is greater in newborns from perchlorate-exposed areas than in newborns from unexposed areas. This is important since people with both low T4 and high TSH are more likely to have real thyroid effects than people with just a high TSH level. For example, a high TSH reading in a person who does not have a correspondingly low T4 level could just reflect normal intra- or inter-individual variability, or laboratory or collection error. Regardless, in each of these studies, T4 was measured in all subjects and at least some evidence was seen in each study that perchlorate was associated with a decreased T4. Given the known relationship between T4 and TSH, these decreases in T4 levels are biologically consistent with the reciprocal increases in TSH that were reported. This consistency provides evidence that the associations identified between perchlorate and increased TSH are real effects and are not solely due to bias from selective TSH sampling.

Other susceptibility factors not accounted for: Another important issue in these studies is the overall lack of data on co-variates that might interact with perchlorate to impact thyroid function. None of these studies specifically investigated potentially susceptible subpopulations such as people who have low iodine intakes, smokers, people with anti-thyroid antibodies, or people with high intakes of nitrate or thiocyanate from foods. Risks of thyroid-related effects may be greater in these groups than in the general population samples that were used in the studies in Table 29.

The TSH surge: For the reasons discussed above, the first 24 hours after birth may be the most relevant period for assessing associations between maternal perchlorate exposure during pregnancy and newborn thyroid hormone levels. One potential complicating factor of measurements collected during this time is the normal physiologic surge in TSH that occurs soon after birth. The exact causes of this surge are unknown, but mechanisms related to cold exposure, the shock of birth, or an acute drop in maternal T4 have been proposed. As shown in Figure 9, TSH levels surge right after birth, typically peak at 30 minutes, then gradually fall to normal levels in the next 24-48 hours (Fisher and Klein, 1981). Several authors have warned against measuring TSH levels during this period because it can lead to an increased rate of false positives when screening for congenital hypothyroidism. In other words, many children who have TSH

readings above 25 µU/mL (the traditional cut-off point for this diagnosis) during the first 24 hours may have normal TSH readings a few days later and not require treatment for congenital hypothyroidism.

However, a clinical diagnosis of congenital hypothyroidism is not the only outcome that should be assessed when looking at the possible impacts of perchlorate. This diagnosis is generally associated with very large changes in thyroid hormone levels and severe effects if untreated. As discussed above, much more subtle changes in thyroid hormones have been associated with cognitive effects in children in several studies (Pop *et al.*, 1999, 2003; Haddow *et al.*, 1999; Klein *et al.*, 2001; Kooistra *et al.*, 2006; Vermiglio *et al.*, 2004). That is, small changes in thyroid hormone levels that are within normal reference ranges have been associated with significant decreases in IQ in children that were not clinically hypothyroid and showed no other evidence of thyroid problems. If researchers only focus on the more severe effect levels that are associated with most cases of congenital hypothyroidism, these more subtle effects will be missed. For this reason, researchers should not only evaluate whether perchlorate is associated with clinically treatable congenital hypothyroidism (and the large TSH changes associated with this diagnosis), but should also investigate whether perchlorate is associated with even smaller changes in thyroid hormone levels. In this regard, while the studies in Table 29 provide little evidence that perchlorate increases the rate of clinical congenital hypothyroidism, they do provide evidence that perchlorate is associated with more subtle changes in newborn thyroid hormone levels.

Health consequences are unknown: The long-term health consequences of the effects seen in Table 29 are unknown. As discussed below, subtle changes in maternal thyroid hormone levels during pregnancy have been linked to cognitive effects in the offspring. This suggests that the fetus is highly sensitive to any changes in thyroid hormone levels during pregnancy. It is unknown whether the neonate is similarly sensitive.

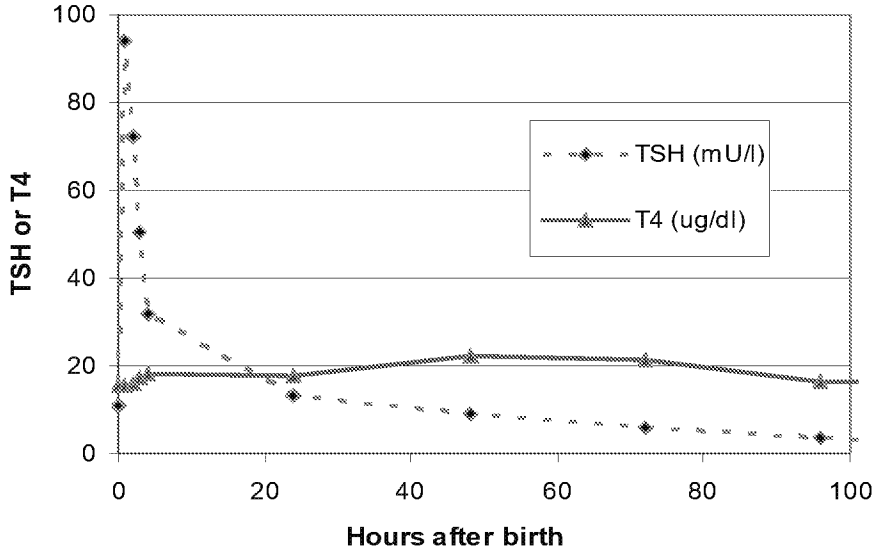
It is possible that the effects seen in Table 29 are also occurring in the fetus. This possibility is consistent with the well-established mechanism of perchlorate, by which a long-term continuous exposure would be expected to cause continuous effects on the thyroid. That is, if the mother is consuming drinking water contaminated with perchlorate during pregnancy, it would be expected that the fetus would be exposed to perchlorate during pregnancy and that some perchlorate would be present in the newborn immediately after birth. If this perchlorate exposure can lead to altered thyroid hormone levels in the newborn (as shown in Table 29), it seems likely that it is also doing so in the fetus. If perchlorate does impact thyroid hormone levels in the fetus, it may cause the same cognitive developmental impacts seen in the studies of maternal thyroid hormone changes during pregnancy (Pop *et al.*, 1999, 2003; Haddow *et al.*, 1999; Klein *et al.*, 2001; Kooistra *et al.*, 2006; Vermiglio *et al.*, 2004). Whether or not this is the case is currently unknown, and further research is needed to

determine if the effects seen in Table 29 are truly associated with long-term health outcomes.

It is possible that the effects reported in Table 29 are simply temporary effects that occur in the day-old newborn and do not occur in the fetus or older child. For example, it is possible that perchlorate somehow only affects the TSH surge, and either does not affect the thyroid at all (i.e., an extra-thyroidal mechanism), or does not affect the thyroid before or after the surge. There are several reasons to believe that this is not the case. First, the data in Table 29 are not consistent with an extra-thyroidal mechanism. If perchlorate were simply causing an increase in TSH by some extra-thyroidal process (that is, without first causing a low T4), then this increase in TSH would be expected to cause an *increase* in T4 levels. This was not seen. Instead, a perchlorate-associated *decrease* in T4 levels was seen in several studies. This suggests that the TSH effects are due to a perchlorate-associated inhibition of T4 production and a direct action on the thyroid gland. Second, TSH peaks about 30 minutes after birth (Figure 9), and the effects reported in Table 29 mostly involve measurements taken after the major part of this peak. For example, in Buffler *et al.* (2006), of all the newborns who had TSH levels measured in the first 24 hours after birth, less than one percent had measurements within the first three hours of birth. This small fraction suggests that any measurements collected during the highest points of the TSH peak had little impact on the Table 29 results. Finally, as discussed above, the hypothesis that the results seen in Table 29 simply represent a short-term temporary effect that occurs only in the day-old newborn (and not in the fetus) is inconsistent with the well-established mechanism in which a continuous dose of perchlorate is known to cause a continuous suppression of thyroidal iodide uptake and a continuous suppression of thyroid hormone production. Given the abundance of data supporting this mechanism, it seems somewhat implausible that some new and completely unknown mechanism, with no evidence to support it, would be causing these effects.

In summary, the data in Table 29 provide a consistent body of evidence linking perchlorate exposure during pregnancy with changes in thyroid hormone levels in the newborn. Currently, the long-term health implications of these effects are unknown. However, given the known mechanism of perchlorate, these effects may represent effects that are also occurring during the fetal period, which is a critical period of thyroid-hormone-dependent brain development.

Figure 9. Changes in Serum Neonatal T4 and TSH Levels by Hour after Birth (Abuid *et al.*, 1973; Cavallo *et al.*, 1980; Fisher and Odell 1969; Sack *et al.*, 1976) [Data are compiled by OEHHA from averaged individual thyroid hormone measurements from the cited studies from infants with blood collected at different times].



Studies of Perchlorate's Effects on Iodide Uptake and Thyroid Hormone

Clinical Dosing Studies

Stanbury and Wyngaarden, 1952. These investigators studied the effect of perchlorate on the discharge and uptake of iodide by the thyroid in Graves' disease patients. To study the effect of perchlorate on the discharge of accumulated iodide, they gave 30 mg of 1-methyl-2-mercaptoimidazole orally to eight patients. A dose of 200 mg of propylthiouracil was given to a ninth patient. One hour later, a tracer of ^{131}I was given. The accumulation of this isotope in the neck was recorded at frequent intervals until it leveled off. At this point, potassium perchlorate doses varying from 3 to 500 mg were given orally in small volumes of water. In each patient except the one treated with propylthiouracil there was a sharp fall in the counting rate within a few minutes after the ingestion. This always occurred within 30 minutes. With smaller doses the discharge of the ^{131}I was incomplete, but doses of 100 mg caused a fall in counting rates nearly equal to the counting rates recorded from the thigh (background). The investigators also reported that a single oral dose of 10 mg perchlorate caused about a 50 percent release of accumulated iodide. Potassium perchlorate doses as low as 3 mg (equivalent to 2.2 mg perchlorate) caused detectable, but incomplete, release of iodide from the thyroid. Assuming an adult body weight of 70 kg, this is equivalent to an oral dose of 31 μg/kg.

A LOAEL is not identified for this experiment because: (a) the number of patients per dose group is not known; (b) it is an acute exposure; (c) the patients suffered from a thyroid disease which might have affected iodide uptake; and (d) the patients were pretreated with drugs (either 1-methyl-2-mercaptoimidazole or propylthiouracil) that may enhance the release of iodide in the thyroid gland by preventing the oxidation of iodide ion to iodine and thyroid hormone synthesis.

To study the effect of perchlorate on the uptake of iodide in the unblocked gland, Stanbury and Wyngaarden (1952) gave 100 mg of potassium perchlorate to three patients and an hour later, tracers of ^{131}I. No thyroid hormone-disrupting drugs were given. Several days later each patient received a control tracer without previous perchlorate. In two cases, the studies were continued for 48 hours, but in the third, an observation period of only five hours was possible after the tracer. For the two patients with the long observation time, the control uptake was about 70 percent of the administered dose at 24 and 48 hours. When the patients were pretreated with potassium perchlorate, the uptakes were approximately 12 percent and 21 percent of the administered tracer dose at 24 and 48 hours following the administration of the tracer.

The duration of the inhibition of iodide uptake after the oral administration of 100 mg of potassium perchlorate (71.8 mg of perchlorate) appeared to be about six hours. Beyond six hours, accumulation of ^{131}I commenced. Durand (1938; as cited in Stanbury and Wyngaarden, 1952) found that at this time approximately half the administered dose of perchlorate has been excreted in the urine.

A LOAEL is not identified for this experiment because: (a) there were only two subjects that completed the experiment; (b) it is an acute exposure; and (c) the patients suffered from a thyroid disease which might have affected iodide uptake by the thyroid.

Godley and Stanbury, 1954. This study reported using potassium perchlorate to treat 24 patients with Graves' disease. Patients were treated with 600 to 1,200 mg/day for at least 11 weeks with a few as long as 52 weeks. Thirteen patients had determinations of the uptake of radioactive iodide by the thyroid both before beginning perchlorate therapy and within two weeks after medication had begun. The mean control uptake was 77.5 percent, with a range from 60.7 to 108 percent. The mean uptake during perchlorate therapy was 15.9 percent, with a range from 3.4 to 38.8 percent.

Bürgi *et al.*, 1974. This investigation studied the effects of perchlorate treatment on the release of endogenous iodide from the thyroid glands of five normal healthy volunteers (three females and two males). The volunteers were given ^{125}I-labeled iodide and ^{131}I-labeled T4 for seventeen days, followed by 3 x 200 mg/day (9.7 mg/kg-day) perchlorate for eight days. Analysis for the two tracers in the urine and serum of the subjects showed that this dose was sufficient to totally block iodide uptake by the thyroid. Additionally, the perchlorate treatment

caused an increase in excretion of non-thyroxine iodine of 65 percent above background.

Brabant *et al.*, 1992. In this study five healthy male volunteers were pretreated with 200 μg/day iodine for four weeks before perchlorate exposure. Iodine exposure was discontinued, and the volunteers were given 3 x 300 mg/day of perchlorate for another four weeks. Serum levels of T3 and T4 were measured at the end of the four-week perchlorate-dosing period. Perchlorate treatment had no effect on serum T3 or T4 levels or on thyroid gland volume. However, serum fT4 and TSH levels were significantly diminished by treatment, and thyroglobulin serum levels were almost doubled, indicating the stress of the treatment on the thyroid hormone balance. The perchlorate treatment also reduced intrathyroidal iodine levels.

In a follow-up study, Brabant *et al.* (1994, as cited in U.S. EPA, 2002) repeated the earlier studies with perchlorate treatment lasting longer than 4 weeks. As a result of the longer treatment, thyroid volumes increased in all subjects, although TSH levels did not increase.

Lawrence *et al.*, 2000. The investigators administered perchlorate to nine healthy male volunteers and monitored the impact on thyroid function. Each subject ingested 10 mg of perchlorate (as potassium perchlorate) dissolved in a liter of spring water for 14 days. Baseline serum TSH, total T4, total T3, 24-hour thyroid ^{123}I uptakes, serum and 24-hour urine perchlorate, and 24-hour urine iodine were determined. All blood and urine tests were repeated on days 7 and 14 of perchlorate administration, and 24-hour thyroid ^{123}I uptakes on day 14 of perchlorate administration. All tests were repeated 14 days after perchlorate exposure was discontinued. No effect of perchlorate was observed on serum T4, T3 and TSH (Table 34). It should be noted that the dietary iodine intake levels of the subjects were rather high, as indicated by the high urine iodine values (Table 35). Because iodide and perchlorate compete for the same receptor site on the sodium-iodide symporter (Wolff, 1998), a high dietary iodine intake may reduce the impact of perchlorate on the thyroid. There was no statistically significant difference in serum perchlorate levels after 7 days and 14 days of exposure, indicating no apparent accumulation of perchlorate in the systemic circulation over that period.

Table 34. The Effect of Perchlorate Administration (10 mg/day, about 0.14 mg/kg-day) for 7 and 14 Days on Thyroid Function Tests (Lawrence *et al.*, 2000)

Time	T4 (µg/dL)	T3 (ng/dL)	TSH (µU/mL)
Baseline	6.6 ± 0.4	136 ± 6	1.05 ± 0.14
Day 7 of perchlorate	6.7 ± 0.4	140 ± 8	1.00 ± 0.17
Day 14 of perchlorate	6.6 ± 0.5	151 ± 6	0.96 ± 0.12
14 days after perchlorate	6.5 ± 0.5	157 ± 9	1.23 ± 0.17

Values are mean ± standard error.

Table 35. Urine and Serum Perchlorate and Iodine Values before, during, and after Ingestion of 10 mg Perchlorate (about 0.14 mg/kg-day) for 14 Days (Lawrence *et al.*, 2000)

Time	Urine perchlorate (mg/24 hr)	Serum perchlorate (µg/mL)	Urine iodine (µg/24 hr)	Serum iodine (µg/dL)
Baseline	<0.5	0	254 ± 69	6.5 ± 0.42
Day 7 of perchlorate	7.7 ± 0.8	0.61 ± 0.02	233 ± 49	6.2 ± 0.34
Day 14 of perchlorate	7.5 ± 1.0	0.59 ± 0.02	385 ± 123	6.4 ± 0.37
14 days after perchlorate	<0.5	0	208 ± 42	6.3 ± 0.57

Values are mean ± standard error.

Lawrence *et al.* (2000) also reported that during perchlorate ingestion, there was a highly significant decrease in the thyroid ^{123}I uptakes at all three time points. In each instance, 150 µCi ^{123}I was administered to a subject and thyroid iodide uptake was measured at 4, 8, and 24 hours. The average decrease below baseline values over all three time points was 38 percent. Two weeks after perchlorate was discontinued, the 24-hour thyroid ^{123}I uptakes were significantly higher than baseline at 4, 8, and 24 hours (Table 36).

Table 36. Thyroid ^{123}I Uptakes before, during, and after Ingestion of 10 mg Perchlorate (about 0.14 mg/kg-day) Daily for 14 Days (Lawrence *et al.*, 2000)

Time	Thyroid ^{123}I uptake– baseline (% of dose)	Thyroid ^{123}I uptake 14 days on perchlorate (% of dose)	Thyroid ^{123}I uptake 14 days after perchlorate was discontinued (% of dose)
4 hours	12.5 ± 1.3	8.2 ± 0.7[a]	16.6 ± 2.4[b]
8 hours	17.3 ± 1.9	10.6 ± 1.0[a]	21.9 ± 2.8[b]
24 hours	23.6 ± 2.6	14.0 ± 1.6[a]	27.1 ± 3.3[c]

[a] $p < 0.01$ vs. baseline and after perchlorate treatment was discontinued
[b] $p < 0.01$ vs. baseline
[c] $p < 0.05$ vs. baseline
Values are mean ± standard error

Lawrence *et al.*, 2001. In a follow-up study, Lawrence *et al.* (2001) administered a daily oral dose of 3 mg of perchlorate to a group of eight healthy male volunteers for 14 days. They reported that the mean 8-hour thyroid radioactive iodide uptake decreased from 13.1 percent to 11.8 percent during perchlorate ingestion. Similarly, the 24-hour thyroid radioactive iodide uptake decreased from 16.1 percent to 14.5 percent, a 10 percent decrease that was not statistically significant. Assuming a default body weight of 70 kg, the dose used in this study is estimated to be 0.043 mg/kg-day.

Greer *et al.*, 2002. Daily oral doses of perchlorate (ClO_4^-) dissolved in 400 mL of water were given to groups of euthyroid human volunteers for 14 days. Subjects (4 male and 4 female; 18-57 years old) of each dose group were exposed to a daily dose of 0.02, 0.1, or 0.5 mg/kg of perchlorate (approximately 1.4, 7, or 35 mg, assuming 70 kg body weight). In a follow-up study, one additional subject of each sex received perchlorate at 0.02, 0.1, or 0.5 mg/kg-day, while six women and one man received a dose of 0.007 mg/kg-day. Subjects drank 100 mL of the perchlorate solution at 4 set times throughout each day. Measurement of 8- and 24-hour ^{123}I thyroid uptakes was performed prior to perchlorate exposure (baseline), on exposure days 2 and 14, and on post-exposure day 15. There was a strong correlation between the 8- and 24-hr uptakes over all dose groups and measurement days. There was no difference between exposure days 2 and 14 in the inhibition of uptake produced by a given perchlorate dose. There was no sex difference. Uptakes measured on post-exposure day 15 were not significantly different from baseline. Table 37 provides the 24-hour thyroid radioiodide uptake data by dose. The researchers measured total T4, fT4, total T3, and TSH in blood sampled throughout the study, and found them to be in the normal range for all subjects. One woman in the lowest dose group had abnormally high TSH on both the screening visit and on exposure day 14. Because of the limited data in the follow-up study, analysis of treatment effects on hormonal levels was confined to the 24 volunteers in the first study. Greer *et al.* (2002) reported no association between perchlorate dose and thyroid

hormone levels except a marginally statistically significant association with a decreased TSH in the 0.5 mg/kg-day dose group.

Table 37. Descriptive Statistics for the 24-Hour Thyroid Radioiodide Uptake Data from Greer *et al.*, 2002

Dose group	Time	Number of subjects in dose group	24-hr uptake (mean ± standard error)	
			Raw (%)	% of baseline
0.007 mg/kg-day	Baseline visit	7	18.1 ± 3.1	
0.007 mg/kg-day	Exposure day 14	7	16.5 ± 1.6	98.2 ± 8.3
0.02 mg/kg-day	Baseline visit	10	18.4 ± 1.2	
0.02 mg/kg-day	Exposure day 14	10	15.2 ± 1.1	83.6 ± 4.1
0.1 mg/kg-day	Baseline visit	10	19.9 ± 2.1	
0.1 mg/kg-day	Exposure day 14	10	11.0 ± 1.6	55.3 ± 3.9
0.5 mg/kg-day	Baseline visit	10	21.6 ± 2.0	
0.5 mg/kg-day	Exposure day 14	10	6.9 ± 0.9	32.9 ± 3.8

Braverman *et al.*, 2006. This investigation was a double blinded, randomized clinical dosing study in which 14 healthy volunteers received either placebo, or 0.5 mg, 1 mg, or 3 mg of potassium perchlorate once per day for six months. Nine of the subjects were women. Serum thyroid hormone and perchlorate levels, and urine perchlorate, iodine, and creatinine levels were measured monthly. Twenty-four hour radioactive iodide uptake (RAIU) was measured at baseline, and at 3 and 6 months of perchlorate ingestion, and one month after dosing was discontinued.

The mean urinary perchlorate level in the five subjects who received 0.5 mg/day was 332.7 µg (± 66.1) per 24 hours. The corresponding amount in the four subjects who received 3 mg/day of perchlorate was 2,079 µg (± 430) per 24 hours. Only one subject receiving the 1 mg dose completed the study and data on this subject was not reported. There were no significant changes in RAIU, T4, free T4 index (FTI), or TSH during or after the dosing period. The mean urinary iodine level in the 3 mg group was very high before the dosing started (322 µg/g creatinine; SD ± 357). This dropped to 192.8 µg/g (SD ± 110.1) one month after the dosing period. The large standard deviation suggests that this could be due to one outlying value, although the individual data on iodine were not shown.

The reason why this study did not find impacts on RAIU similar to other studies is unknown, although the authors note that this could be due to the small number of subjects, differences in dosing regimens (once daily versus semi-continuous), or the possibility that the NIS may be up-regulated as an adaptive response to long-term exposure. Given the fact that various metabolic and physiologic functions

have been shown to be less well developed and less effective in young children than in adults (Ginsberg *et al.,* 2002; Ginsberg *et al*., 2004), if chronic perchlorate exposure does cause the NIS to up-regulate, this might be less effective in young children than in adults.

Occupational Studies

Gibbs *et al*., 1998. This study monitored triiodothyronine resin uptake (T3U), total serum T4, FTI, and TSH levels in 18 workers occupationally exposed to ammonium perchlorate in air before and after a work shift. They also similarly monitored 83 workers who were not exposed. Based on the thyroid function test results collected, the authors concluded that exposure to a mean of 36 μg/kg-day ammonium perchlorate (ranging from 0.2 to 436 μg/kg-day) was not a significant predictor of the cross-shift change in any of the thyroid parameters. Given the relatively long serum half-life of T4 in adult humans (5-9 days) (U.S. EPA, 1998b), it would be very unlikely that serum T4 levels would exhibit a change over a single work shift.

Gibbs *et al*. (1998) also evaluated the thyroid function test results of workers exposed to ammonium perchlorate based on their working-lifetime dose estimates. They reviewed personnel records and employees were interviewed to determine the number of years worked in each of the seven exposure groups. An average of 2,000 hours worked yearly was assumed. Each subject's working-lifetime cumulative dose was then estimated as:

$$\sum [\text{mean group exposure}] \times [\text{years in exposure group}] \times 2{,}000$$

No significant correlations with estimated lifetime cumulative perchlorate dose were detected with any of the thyroid function measures (T3U, T4, FTI, and TSH levels). However, the tenure of the workers ranged from 1 to 27 years, while thyroid hormone levels are most likely to be affected by relatively recent perchlorate exposures (probably in the range of 1-3 months). Because of this, cumulative dose over a long period of time may not be the best metric for characterizing the effect of perchlorate exposure on thyroid hormone levels.

Lamm *et al*., 1999. This is a cross-sectional study of two similar worker populations from the same industrial complex: ammonium perchlorate production workers and sodium azide production workers. A total of 37 workers were exposed to airborne ammonium perchlorate, 35 males and two females. Twenty-one workers from the azide production plant served as the control group. Perchlorate exposure was measured using full-shift breathing zone personal air samplers for total as well as respirable perchlorate particles. Urinary perchlorate concentration was assessed at the beginning and end of the 12-hour shift in which the perchlorate exposure was measured. Post shift serum samples were collected for measurements of T4, T3, TSH, and anti-thyroid antibodies. The authors reported that there were no differences in thyroid function tests between workers in the azide and perchlorate plants or between the azide workers and

any of the three perchlorate-exposure groups (Table 38). Based on these data, a NOAEL of 0.48 mg/kg-day (33.6 mg/day divided by 70 kg) can be estimated. However, this data set has several limitations: (a) small sample size, (b) high dietary iodine intake among the workers, and (c) given the short biological half-life of perchlorate (approximately 8 hour), the exposed workers might recover from the effects of perchlorate during off-shift hours. Using the medical examination and questionnaire findings, Lamm *et al.* (1999) reported that worker exposures to perchlorate in the plant were not found to be associated with thyroid abnormalities.

Table 38. Perchlorate Exposures and Thyroid-Function Parameters, by Plant and Exposure Groups (Adapted from Lamm *et al.*, 1999)

Group	Total airborne perchlorate (mg/day)	Respirable airborne perchlorate (mg/day)	Absorbed dose (mg/shift)[a]	T4 (µg/dL)	T3 (ng/dL)	TSH (µU/mL)
Normal range				5 to 11	87 to 178	0.45 to 4.5
Azide worker	0.014±0.012 (n=4)	0.021±0.014 (n=6)	0.88±1.17 (n=21)	6.73±1.48 (n=21)	142.5±17.5 (n=21)	3.14±1.87 (n=21)
Perchlorate worker A	0.337±0.187 (n=6)	0.091±0.095 (n=11)	3.98±2.69 (n=14)	7.13±1.58 (n=13)	148.4±25.2 (n=13)	2.68±1.14 (n=12)
Perchlorate worker B	6.57±7.14 (n=2)	0.601±0.671 (n=7)	10.9±8.7 (n=8)	7.34±1.12 (n=8)	152.1±23.2 (n=8)	2.41±1.27 (n=8)
Perchlorate worker C	59.4±53.6 (n=12)	8.59±9.39 (n=14)	33.6±14.5 (n=14)	7.03±1.30 (n=15)	152.1±20.4 (n=15)	3.33±2.34 (n=15)

[a]Derived from urinary perchlorate concentration
Values are mean ± standard deviation

Braverman *et al.*, 2005. This was an investigation of RAIU and thyroid hormone levels in 29 workers employed in the same perchlorate production facility used in Lamm *et al.* (1999) and in 12 volunteers who did not work at the plant. All subjects were Caucasian males, and eight workers and two controls were smokers. The normal schedule for employees at the plant was to work three 12 hours shifts on three consecutive days and then have three days off work. Serum levels of perchlorate, thiocyanate, nitrite, T3, T4, FTI, and TSH and urine concentrations of perchlorate and iodine were measured just before (pre-shift) and just after (post-shift) the three day shift. Mean serum perchlorate levels in the workers increased from 2 µg/L to 838 µg/L from pre-shift to post-shift. RAIU decreased from 21.5 percent pre-shift to 13.5 percent post-shift (p-value for the difference < 0.01). The authors estimated perchlorate intakes based on differences in pre- and post-shift serum levels and used these estimates to plot dose-response relationships with RAIU. Figure 4 of their paper shows that perchlorate and RAIU relationship in this study was similar to that reported in Greer *et al.* (2002) and Lawrence *et al.* (2000, 2001). Interestingly, the RAIU

levels in the non-worker control subjects (14.4 percent) was significantly lower than the pre-shift level of the workers (21.5 percent, $p < 0.01$ compared to controls) and very similar to that of the post-shift level of the workers (13.5 percent, $p = 0.64$ compared to controls). The reason for this is unknown, although the authors note that this might be consistent with an apparent rebound increase in RAIU that has been noted in other studies. Post-shift workers had a slight but statistically significant increase in T3, T4, and FTI. The reason for this is unknown, although the authors hypothesize it may be due to a decreased iodine concentration in the thyroid enhancing the thyroid's response to TSH.

Although serum levels of thiocyanate and nitrate and urinary levels of iodine were measured, no data were presented on possible interactions between these variables and perchlorate on RAIU or thyroid hormone levels. The authors reported that exposure caused no statistically significant change in serum thiocyanate and nitrate levels but was associated with a statistically significant increase in urinary iodine:creatinine ratio. The pre-shift vs. just-after-shift means were 148 µg/g and 230 µg/g, respectively ($p = 0.02$). The mean urinary iodine:creatinine ratio in controls was 296 µg/g. The authors hypothesize that the increase in urinary iodine might have been a result of less dietary iodine being concentrated in the thyroid with perchlorate exposure.

Environmental Studies

Tèllez Tèllez *et al.*, 2005. Neonatal and maternal thyroid function were assessed in subjects from the following three cities (mean perchlorate levels in drinking water) in northern Chile: Taltal (100-120 µg/L), Chañaral (5-7 µg/L), and Antofagasta (non-detectable: <4 µg/L). The neonatal results are discussed in a preceding section. Serum fT4 and TSH measurements were collected from 184 women at two prenatal visits and one post-partum visit. No difference in mean fT4 or TSH was seen across the three cities at any of the three visits. For example, on the first prenatal visit (a mean of about 16 weeks gestation), the mean fT4 (in ng/dL) in the low, medium, and high perchlorate cities were 0.97 (SD ± 0.15), 0.95 (± 0.13), and 0.99 (± 0.13) (Kruskal-Wallis $p = 0.19$). Regression analyses showed no association between urinary perchlorate excretion and levels of fT4, TSH, and T3, although details of this analysis, such as whether urine concentrations were adjusted for urine dilution, or whether perchlorate concentrations were log transformed, were not reported. Maternal goiter was seen in all cities and increased from the first prenatal visit to the post-partum visit in both Taltal and Antofagasta, although the increase was greater in Taltal (from 9.4 percent to 22.5 percent) than in Antofagasta (from 8.7 percent to 11.1 percent).

As discussed in the section reviewing the neonatal findings of this study, maternal iodine levels were very high and it is possible that this may have protected the infants and the mothers from the impacts of perchlorate. Other factors that were also discussed above include: 1) similarity of the urinary perchlorate concentrations across the unexposed, low, and high exposure cities;

2) cesarean-section rates were markedly different across cities (cesarean section rates may impact chemical-thyroid hormone associations (Herbstman *et al.,* 2008)) ; 3) 45 percent of women from the exposed city gave birth in the unexposed city; and 4) there were few smokers (a common source of thiocyanate) and no data on thiocyanate levels. As discussed below, iodine, thiocyanate, and smoking may be important susceptibility factors in perchlorate-exposed women.

Gibbs and Van Landingham, 2008. This study involved a re-analysis of the data collected in the Tèllez Tèllez *et al.* (2005) study. In the previous paper, a regression analysis was done but very few results and details were provided. Most of the results presented in the previous paper were comparisons of mean thyroid hormone levels in each of the three cities. This may have diminished the ability of the study to identify a true effect since there was substantial overlap in urinary perchlorate concentrations across the cities. In this 2008 Letter to the Editor, Gibbs and Van Landingham used individual data on urine perchlorate, urine iodine, serum fT4 and TSH, and an interaction term for iodine and perchlorate in a linear regression analysis involving 150 women from the previous Tèllez Tèllez *et al.* (2005) study. Serum free T4 was entered into the model as fT4 unchanged or as $1/fT4^{½}$. The latter was used in order to achieve a normal distribution of the residuals, which is an assumption of the linear regression model. No associations were identified between urine perchlorate and fT4 or TSH (coefficients were only provided for statistically significant results). In addition, no associations were found in analyses restricted to subjects with urinary iodine levels below 100 µg/L, although this included only 16 subjects. Interestingly, in the analysis using the normalized fT4 variable (i.e., $1/fT4^{½}$), a statistically significant positive interaction was seen for iodide and perchlorate (regression coefficient (β) for the urinary iodide-perchlorate interaction = 6.26×10^{-7}; $p < 0.0001$). Given the apparent complexity of these analyses, and the lack of detail in this Letter to the Editor, the clinical meaning of this coefficient is difficult to interpret. The authors note that the coefficient for perchlorate itself was not significant in this analysis; however, the inclusion of an interaction term which includes perchlorate invalidates the use of the perchlorate regression coefficient for assessing any association with the dependent variable (Greenland, 1998). If these findings truly represent a perchlorate-iodide interaction, they would support the findings seen in Blount *et al.* (2006) described in the next section.

Blount *et al.*, 2006 and Steinmaus *et al.*, 2007. These are two studies which used data from the same cross-sectional investigation of urinary perchlorate levels and serum levels of thyroid hormones in 2,299 men and women ≥ age 12 years who took part in the 2001-2002 NHANES. NHANES is conducted by the National Center for Health Statistics of the Centers for Disease Control and Prevention (CDC) and is designed to assess the health and nutrition status of the non-institutionalized population of the U.S. This survey involves a complex multistage sampling design with some over-sampling in certain areas and among certain subgroups, but is designed to provide results that are nationally

representative. Information that is collected as part of this survey includes questionnaire data on demographic information, smoking, health history, and medication use. A single serum measurement of T4 and TSH and a single measurement of urinary perchlorate and iodine concentration were also collected. Other information collected included urinary creatinine, thiocyanate, and nitrate; and serum levels of albumin, cotinine, and c-reactive protein. Blount *et al.* (2006) assessed the relationship between serum thyroid hormone levels and urine perchlorate concentrations using a linear regression analysis adjusted for potential confounding variables and co-variates including age, urinary creatinine, estrogen use, c-reactive protein, cotinine, ethnicity, menopause, premenarche, pregnancy, fasting time, body mass index, and kilocalorie intake. Several factors including urinary perchlorate and creatinine and serum TSH were log-transformed to normalize their distributions. Exclusions included subjects with missing data on co-variates, a history of thyroid disease, current use of thyroid medications, extreme values of T4 or TSH (n = 3), and subjects missing perchlorate measurements. No association was found between T4 or TSH and perchlorate in men. In women, separate analyses were done for women with urinary iodine levels above and below 100 µg/L. This level was chosen since it is used by the World Health Organization to define iodine deficiency in a population. Thirty-seven percent of the women in this study had urinary iodine levels below 100 µg/L. The results of the analyses in women are shown in Table 39. A statistically significant association was seen between increasing TSH and increasing perchlorate in women with iodine levels above and below 100 µg/L. A statistically significant association was also seen between decreasing T4 and increasing perchlorate in women with urinary iodine levels below 100 µg/L, but not in women with iodine levels above 100 µg/L. The magnitude of this association ($\beta = -0.8917$) suggests that a ten-fold increase in urinary perchlorate (roughly the difference between the 10^{th} and 90^{th} percentiles) is associated with about an 11 percent decrease in T4. In pregnant women, this level of decrease is a little less than half of the decrease in T4 or fT4 associated with an average seven percent decrease in cognitive function in the offspring (see Table 20).

Table 39. Associations between Thyroid Hormone Levels and the Logarithm of Urinary Perchlorate in Women with High and Low Levels of Urinary Iodine (Blount *et al.*, 2006)

	Number of Subjects	Regression Coefficient (β)	Standard Error of β	p-value
Urine iodine < 100 µg/L				
T4	348	-0.8917	0.1811	<0.0001
Logarithm of TSH	356	0.1230	0.0373	0.0010
Urine iodine ≥ 100 µg/L				
T4	724	0.2203	0.3687	0.5503
Logarithm of TSH	697	0.1137	0.0506	0.0249

Differences in the numbers of subjects with an iodine category are due to differences in the number of subjects missing data on co-variates in each analysis. Except for perchlorate and creatinine, only co-variates with p-values < 0.10 were retained in each model.

Steinmaus *et al.*, 2007 used the same NHANES database and assessed whether other NIS inhibitors such as thiocyanate and nitrate might interact with perchlorate and iodine to affect thyroid hormone levels. Associations assessed by linear regression between thyroid hormones and urinary perchlorate were stratified by categories of nitrate, thiocyanate, smoking, and cotinine. Smoking and cotinine were evaluated since smoking is a major source of thiocyanate in many people and serum cotinine has been used in past studies as a biomarker for smoking intensity. The results of these analyses are shown in Table 40. In analyses of women with urinary iodine levels below 100 µg/L, regression coefficients between decreasing T4 and increasing urinary perchlorate were greater in smokers, those with high cotinine, and those with high thiocyanate levels than in non-smokers, those with low cotinine, and those with low thiocyanate, respectively. The magnitude of this association (β = -1.66) suggests that a ten-fold increase in urinary perchlorate (roughly the difference between the 10^{th} and 90^{th} percentiles) is associated with about a 20 percent decrease in T4. In pregnant women, this level of decrease is only a little lower than the decrease in T4 or fT4 associated with an average seven percent decrease in cognitive function in the offspring (see Table 20). These findings provide evidence that thiocyanate interacts with perchlorate and low iodine levels to decrease T4 production. The fact that similar effects are seen with all three methods used to categorize thiocyanate exposure (urine thiocyanate, serum cotinine, and smoking history) provides strong evidence that these findings are not due to chance. Interactions with TSH were seen in some analyses but not all and were not as clear as those seen for T4.

Table 40. Association between the Logarithm of Urinary Perchlorate (µg/L) and Serum T4 (µg/dL) and the Logarithm of TSH (µg/dL) in Women with Urinary Iodine < 100 µg/L, 2001-2002 NHANES (Steinmaus *et al.*, 2007)

Abbreviations: β, regression slope; ND, non-detectable; SE, standard error.
[a]T4 models were adjusted for fasting time, kcal, body mass index, c-reactive protein, nitrate, race, estrogen use, and pregnancy. T4 model with cotinine was also adjusted for menopause status.
[b]LogTSH models adjusted for age, fasting time, body mass index, race, premenarche, and lactation. LogTSH model with smoking status also adjusted for menopause status.
[c]Smoking data not available on all women and recent former smokers are excluded.
[d]Medium category includes all subjects with serum cotinine levels between 10 ng/mL and non-detectable.
[e]Thiocyanate categories based on tertiles in all women age 12 or older.

Analysis of Blount *et al.* (2006) and Steinmaus *et al.* (2007)

Blount *et al.* (2006) and Steinmaus *et al.* (2007) are key studies supporting two of the potential susceptibility groups identified by OEHHA (women with low iodine and women with high thiocyanate) and thus were evaluated in further detail. These studies have several strengths. First, they are based on individual rather than ecological data on perchlorate exposure and thyroid hormone levels. Second, information on a variety of potential confounders was collected and could be controlled for. Third, the studies involved a fairly large sample size, so the researchers could assess certain important susceptibility factors, like iodine status, sex, and thiocyanate intake that were not assessed in other studies. Some occupational and clinical studies, although they involved higher perchlorate exposure levels, may have missed the effects seen in Blount *et al.* (2006) and Steinmaus *et al.* (2007) because they did not specifically investigate susceptible groups. Fourth, the p-values for the associations identified were well below 0.05,

signifying that the probability these findings were due to chance is fairly low. Finally, the findings are biologically plausible in that they are consistent with the mechanism and direction by which perchlorate, iodine, and thiocyanate are all known to affect T4 and TSH levels.

There are also several potential concerns regarding these data. First, the studies are based on cross-sectional data and single measurements of urinary perchlorate, urinary iodine, and serum thyroid hormones. This could lead to some misclassification of true long-term exposure and thyroid hormone status. However, the half-life of perchlorate is short (about 8 hours in Greer *et al.,* 2002), and perchlorate seems to affect the thyroid fairly rapidly (less than one day in rats in Yu *et al.,* 2000). Because of this, shorter-term measures of perchlorate and thyroid status are probably better for assessing true associations than long-term measures. Also, since specimens were collected similarly in all subjects, any error resulting from not using the most relevant measure of perchlorate and thyroid hormone status would most likely cause a non-differential misclassification and likely bias towards the null, not towards the positive effects identified. The use of total T4 rather than free T4 (the physiologically available form) may also cause some misclassification, but again this would be expected to be non-differential and towards the null.

Urinary iodine levels for an individual can vary throughout the day and from day to day. Because of this fluctuation, it has been argued that measuring a single spot urinary iodine level is a poor reflection of an individual's overall, long-term iodine status. However, studies show that moderate to fairly strong correlations exist between single spot fasting urinary iodine concentrations and 24-hour urinary iodine concentrations, the recommended method for evaluating iodine deficiency in an individual (see Table 41). The fact that these correlations are not near zero suggests that while spot urinary iodine measurements may be associated with some misclassification, they still do provide at least some indication of true long-term iodine status in most people.

Table 41. Correlation Coefficients (R) of 24-Hour Urinary Iodine Levels with Single Spot Urinary Iodine Concentrations (µg/L) and Urine Iodine/Creatinine (I/Cr) Ratios

Author/Year	Location	N	R (for µg/L)	R (for I/Cr)
Konno *et al.*, 1993	Japan	22	0.83 ($p < 0.001$) (unknown)	0.699

[a]Pearson correlation coefficient involves an assumption that the data are normally distributed; distortions of the true correlation can occur if they are not.

Urinary creatinine levels are commonly used to adjust urinary levels of other chemicals for urine dilution. Lamm *et al.* (2007) analyzed the NHANES 2001-2 data using the iodine:creatinine (I/Cr) ratio rather than iodine concentration and found no association between T4 and perchlorate in women with low I/Cr values. However, there are some concerns about the validity of using I/Cr ratios. The first is whether or not dividing a urinary analyte concentration by urine creatinine concentration actually increases the accuracy of classifying true long-term exposure to that analyte, either in an individual or in a group. Increasing evidence suggests that it does not (at least for some chemicals). As seen in Table 41, several studies show that correlations between I/Cr ratios and 24-hour iodine levels are no better than those seen with unadjusted urine iodine concentrations. Studies of other chemicals in urine have also shown that creatinine adjustment does not improve correlations with 24-hour urine levels or with biomarkers of effect (Hinwood *et al.*, 2002; Biggs *et al.*, 1997). One study presented in Table 41 did find an increased correlation coefficient after creatinine adjustment (Knudsen *et al.*, 2000). However, unlike the other studies in this table, this one presented Pearson correlation coefficients. These assume that variables are normally distributed (which many times urinary iodine levels are not) and can give highly distorted results if this assumption is not met.

As discussed above, the most likely bias from misclassifying true long-term iodine status would be bias towards finding no effect. The fact that the perchlorate-T4 association goes away in analyses stratified by I/Cr ratios suggests that the use of I/Cr leads to much more, not less, misclassification of true iodine status. One possible reason for this is that the concentration of creatinine in urine depends on many factors other than urine dilution. Dividing urine iodine concentration by urine creatinine concentration creates a variable with two components: iodine and creatinine. Between-person differences in I/Cr will depend on both the variability in iodine and the variability in creatinine. Thus, I/Cr is not only dependent on iodine excretion and iodine status, but is also dependent on creatinine excretion and all of its determinants. Studies have shown that while urine dilution may be a major determinant of urinary creatinine levels *within* an individual, factors such as age, sex, genetics, physical activity, muscle mass, and diet are major determinants of differences in creatinine excretion *between* individuals and may play an even greater role than urine dilution in determining inter-individual variation in urine creatinine levels (Barr *et al.*, 2005). People who have very high or very low levels of urine creatinine because of factors other than urine dilution will have their true iodine status misclassified if I/Cr ratios are used. Because urine creatinine concentration is dependent on all of these factors, using it to adjust for urine dilution may introduce a degree of misclassification of true iodine status which could overwhelm any improved accuracy that results from correcting for urine dilution. Based on these factors, several authors have concluded that I/Cr ratios should not be used for assessing iodine status (Bourdoux, 1993; Furnee *et al.*, 1994; Thomson *et al.*, 1996, 1997; Rasmussen *et al.*, 1999).

In summary, most evidence suggests that the findings in Blount *et al*. (2006) are not due to misclassification of exposure or outcome, and are not due to the cross-sectional nature of the study design. In fact, given that the most likely direction of the bias caused by these factors is towards finding no effect, if any misclassification of perchlorate, iodine, T4, and TSH could be corrected, the associations identified in these studies are likely to be even stronger than those reported.

Another potential problem with cross-sectional data is that one cannot be assured of the appropriate temporality; that is, that the exposure came before and caused the outcome, rather than the outcome coming before and causing the exposure. However, given the abundance of data showing that perchlorate can lead to a decrease in thyroid hormone levels, and no evidence for the opposite effect, it seems highly unlikely that the Blount *et al.* (2006) and Steinmaus *et al.* (2007) results represent an effect of thyroid hormones on urinary perchlorate levels.

Another potential concern in Blount *et al.* (2006) and Steinmaus *et al*. (2007) is the possibility of confounding. Although analyses included a number of potential confounding variables, some factors associated with thyroid hormone levels were not adjusted for. Importantly though, in order for a variable to cause confounding it must be associated with the exposure and the outcome of interest. If it is not associated with both, it cannot be a confounder. In addition, confounding should not be viewed as a qualitative issue, but rather as a quantitative problem. As stated in Rothman and Greenland (1998a), "It is the amount of confounding rather than the mere presence or absence that is important...." In order for a variable to cause important confounding, it must be strongly (not weakly) related to the exposure and outcome. If a variable is only moderately or weakly associated with the exposure and outcome it will likely cause little confounding and have only minimal impacts on results and overall conclusions (Axelson, 1978). It would be wrong to suggest that a variable that is unassociated with, or only weakly associated with, T4 or urinary perchlorate likely caused the relatively strong association between T4 and perchlorate identified by Blount *et al*. (2006).

In both the Blount *et al*. (2006) and Steinmaus *et al*. (2007) studies, the fully adjusted regression coefficients between T4 and perchlorate were very similar to the unadjusted coefficients. This suggests that although the potential confounders included in the models may have been related to the exposure, or to the outcome, or to both, none were related strongly enough to cause significant confounding. The impact of these variables at causing confounding can be assessed by looking at the effect of each one individually. Table 42 presents the results of the perchlorate-T4 linear regression analysis before and after each potential confounder is removed from either the unadjusted or fully adjusted model. As can be seen, removing any of the individual co-variates had less than a 20 percent effect on the magnitude of the perchlorate-T4 regression coefficient.

Table 42. Impact of Each Potential Confounding Variable on the Perchlorate-T4 Regression Coefficient (β) in Steinmaus *et al.* (2007)[a]

	Remove one variable at a time from the fully adjusted model			Add a single variable to the unadjusted model[b]

BMI, body mass index

[a]All of the available potential confounders were entered into the model presented here. In Steinmaus *et al.* (2007) only those with p-values < 0.20 were added to and retained in the model. All analyses include the NHANES sample weights.

[b]The independent variables in the unadjusted model are the logarithm of perchlorate and the logarithm of creatinine. This is the coefficient with creatinine removed.

Some factors that might be related to thyroid hormone levels were not adjusted for in the NHANES studies (e.g., anti-thyroid hormone antibodies, PCBs, physical activity, menstruation disturbances). However, OEHHA is not aware of any evidence that these factors are associated strongly enough with perchlorate exposure that they would cause important confounding.

Nitrate has also been shown to be an NIS inhibitor. However, analyses of the NHANES 2001-2 urinary concentration data showed no evidence of an interaction of nitrate with perchlorate and iodine. The reasons for this are unknown, although some possible explanations are:

- Urine nitrate may not be an adequate reflection of serum nitrate or the concentration of nitrate reaching the thyroid gland and NIS.

- Variability in nitrate levels may be greater than variability in perchlorate and thiocyanate. Increased variability would decrease the statistical power of the study to find true associations.
- The *in vitro* studies in human cell lines which have assessed the relative potencies of iodine, perchlorate, thiocyanate, and nitrate may not be relevant to *in vivo* exposures.
- The nitrate exposures in NHANES may not have been high enough to affect thyroid function. In a clinical trial, a nitrate dose of 15 mg/kg-day for 28 days did not decrease thyroidal iodide uptake or impact thyroid hormone levels in 10 healthy volunteers (Hunault *et al.,* 2007). This intake level is 5-20 times or more higher than average nitrate intakes reported in several populations in Europe and the U.S. (OEHHA, 2000).

As a whole, although some of the details of the findings of Blount *et al.* (2006) and Steinmaus *et al.* (2007) remain unexplained, a thorough analysis of the major tenets of causal inference show that the overall results are generally consistent with known mechanisms and not likely due to chance, confounding, or other bias.

Pearce *et al.*, 2010. Urinary perchlorate and iodine concentrations and serum thyroid hormone levels were measured during the first trimester of pregnancy in 480 euthyroid women from Cardiff, Wales and 526 euthyroid women from Turin, Italy. Median urinary iodine levels were 117 µg/L in Cardiff and 50 µg/L in Turin. Median perchlorate levels were 2.6 µg/L (range, 0.3-49) in Cardiff and 5.2 µg/L (range, 0.2-168) in Turin. No correlation was found between urinary perchlorate concentrations and maternal T4 or TSH in either city. Analyses restricted to the large subset of women with urinary iodine levels below 100 µg/L gave similar results. Urine thiocyanate levels were low, much lower than those commonly found in the U.S. The median urine thiocyanate levels in Cardiff and Turin were 470.5 and 372.5 µg/L, respectively. In the NHANES study discussed above (Steinmaus *et al.,* 2007), the strongest perchlorate-thyroid hormone associations were found with thiocyanate levels in the upper tertile (i.e., above 1800 µg/L), and clear associations were not found with thiocyanate levels below 751 µg/L. In this regard, the Pearce *et al.* (2010) findings are consistent with those of Steinmaus *et al.* (2007).

Pearce *et al.*, 2012. In this cross-sectional study, urinary concentrations of perchlorate, iodine, and thiocyanate, and serum concentrations of TSH, free thyroxine (fT4), free triiodothyronine (fT3), and thyroperoxidase (TPO) antibodies were measured in 134 pregnant women from Athens, Greece, at a mean gestational age of 10.9 weeks (SD ± 2.3 weeks). Mean (± SD) concentrations were 6.5 µg/L (±11.2 µg/L) for perchlorate, 440 µg/L (± 318 µg/L) for thiocyanate, and 135 µg/L (± 77 µg/L) for iodine. In unadjusted analyses, a negative correlation was found between urine perchlorate and serum fT4 in all women (Spearman correlation coefficient (R) = -0.19; p=0.03) and in the subgroup of 50 women with iodine levels below 100 µg/L (R= - 0.23; p=0.09). However, in

multivariable regression modeling, with adjustments for urinary thiocyanate, urinary iodide, TPO titer, gestational age, and maternal age, a clear relationship between the logarithm of urinary perchlorate (µg/L) and the logarithm of serum fT4 (pmol/L) was not seen (regression coefficient (β) = -0.007; p=0.8). Gestational age was found to be inversely associated with fT4 in multivariable regression analyses (β =-0.003; p=0.002 for the association between gestational age in days and the logarithm of serum fT4), and positively correlated with urinary perchlorate concentration (R = 0.18; p=0.04). Based on these results, the authors hypothesized that gestational age appeared to be a confounder in the apparent correlation between urine perchlorate and serum fT4. The reason why gestational age was associated with urine perchlorate is unknown. In addition, unadjusted regression results were not presented, so regression analyses with and without adjustment for gestational age could not be compared. Mean thiocyanate concentrations were below those where the strongest associations between increasing urinary perchlorate and decreasing serum total thyroxine (TT4) were seen in NHANES (Steinmaus *et al.,* 2007). Associations between urinary perchlorate and TSH were not seen in correlation or regression analyses.

Leung *et al.*, 2012. Perchlorate, thiocyanate, and iodine in breast milk, and in maternal and breastfed infant urine (aged 1-3 months), and serum thyroid hormone concentrations in infants were measured in 64 infant-mother pairs from the Boston area. Median (range) perchlorate concentrations were 4.4 µg/L (0.5-29.5 µg/L) in breast milk, 3.1 µg/L (0.2-22.4 µg/L) in maternal urine, and 4.7 µg/L (0.3-25.3 µg/L) in infant urine. Urine iodine concentrations were 101.9 µg/L (27-570 µg/L) in mothers and 197.5 µg/L (40-785 µg/L) in infants. In multivariable regression analyses which included breast milk, maternal urine, and infant urine thiocyanate concentrations, no evidence of an association was seen between breast milk, maternal urine, and infant urine perchlorate concentration and infant serum fT4 (logarithm transformed) or TSH (logarithm transformed). For example, the regression coefficient between infant urinary perchlorate concentrations and the logarithm of infant serum fT4 concentrations was 0.004 (p=0.12) (units not provided). The authors noted that they were not able to achieve their targeted enrollment of 275 mother-infant pairs, and state that, "The recruited study population was underpowered to determine the statistical significance of perchlorate and thiocyanate exposures on serum infant thyroid function."

Mendez and Eftim, 2012 and Steinmaus *et al.*, 2013. Both of these studies used data from the 2007-8 NHANES to investigate associations between urinary perchlorate concentrations and serum concentrations of thyroid hormones. Compared to the original 2001-2 NHANES discussed above (Blount *et al.,* 2006; and Steinmaus *et al.,* 2007), serum thyroid hormone and urinary perchlorate concentrations were collected from a substantially larger number of subjects (5,921 versus 2,268) in NHANES 2007-8. In generalized additive mixed models, Mendez and Eftim (2012) reported associations between increasing creatinine-adjusted urinary perchlorate concentrations and decreasing serum TT4 and decreasing fT3 concentrations in the entire cohort and in separate analyses of males and females. For example, regression coefficients between perchlorate

(µg/L) and TT4 (µg/dL) in males and females were -0.0195 (p=0.01) and -0.0192 (p=0.03), respectively. Both perchlorate and TT4 levels were log-transformed. Similar associations were seen for fT4 in males but not in females. Additional co-variates in the models included age, ethnicity, tobacco smoking, medication use, body mass index, serum cotinine, and urinary iodine, thiocyanate, and phthalate ester metabolites. The authors stated that the models predicted reductions in serum TT4 of 0.46 µg/dL for males and 0.48 µg/dL for females (roughly a 6 percent reduction) for an increase in urinary perchlorate from the 5th to 95th percentiles. The Mendez and Eftim (2012) analyses were limited to only those 1,877 subjects who had data on urinary perchlorate, serum thyroid hormones, and urine phthalate ester metabolites. The authors noted that a previous study involving an overlapping subset of the NHANES subjects had identified a correlation between thyroid hormone levels and urinary phthalate ester and bisphenol A concentrations, "thus controlling for phthalate ester excretion was necessary to estimate the independent impact of perchlorate on hormone levels." Strong evidence of this type of confounding was not reported however.

In Steinmaus *et al.* (2013), subjects in NHANES 2007-8 were categorized into exposure groups based on their urinary perchlorate, iodine, and thiocyanate concentrations, and mean serum thyroxine concentrations were compared between groups. Analyses were adjusted for age, sex, and urine specific gravity. Subjects with urine perchlorate concentrations in the upper tertile (n=1,939) had TT4 concentrations that were 5 percent lower (mean difference=0.40 µg/dL, 95% CI, 0.14-0.65) than subjects in the lower tertile (n=2,084). Subjects with urine perchlorate in the upper tertile, urine thiocyanate in the upper tertile, and urine iodine concentrations below 100 µg/L combined (n=62) had TT4 concentrations 12.9 percent lower (mean difference=1.07µg/dL, 95% CI, 0.55-1.59) than subjects with lower perchlorate, lower thiocyanate, and adequate iodine concentrations (n=376). Similar findings were seen for fT4. Adjustments for other potential confounders including smoking, thyroid antibodies, fasting time, and medication use, or exclusions based on pregnancy, lactation, thyroid disease, or thyroid medication use had little impact on results. Overall, these results suggest that concomitant exposure to perchlorate, thiocyanate, and low iodine markedly reduces thyroxine production.

Bruce *et al.*, 2013. Bruce *et al.* (2013) used data from the same NHANES study as Blount *et al.* (2006) and Steinmaus *et al.* (2007), but the original serum samples were re-analyzed for serum TT4, TSH, fT4, thyroglobulin, thyroglobulin antibody, thyroperoxidase antibody, and several other factors. Measurements of fT4, thyroid antibodies, and some other factors were not available for the earlier analyses. In addition, the authors evaluated the role of perchlorate, thiocyanate, and nitrate in iodide uptake inhibition using perchlorate equivalent concentrations (PECs). The premise of this method is that the relative potencies of each agent on inhibiting iodide uptake in the thyroid can be multiplied by the concentrations of these agents in urine to determine their total combined impact on iodide uptake and thyroid hormone production. The authors reported that the overall PEC was weakly and negatively associated with serum TT4 levels. Using the

logarithm of total PEC and logarithm of TT4, the regression coefficient (β) was -0.0251 (p=0.020). However, similar associations were not seen for the logarithm of TSH (β = -0.0182; p=0.665) or free thyroxine (β = -0.0066; p=0.554). Other variables in the regression models included age, fasting time, body mass index, calories, ethnicity, serum albumin, use of certain medications, and other factors.

Importantly, the relative potencies used in this paper were based on the results of the Tonacchera *et al.* (2004) laboratory study. In this study, human sodium-iodide symporter (NIS) was transfected into Chinese hamster ovary cells, which were then seeded in 24-well plates and cultured in Dulbecco modified Eagle's medium containing 10% fetal calf serum. When the cells reached 100% confluence, the medium was removed, and the cells were washed with physiologic solution and combined with 500 mL buffer A (Hanks' balanced salt solution containing 0.5% bovine serum albumin and 10 mmol N-2-hydroxy-ethylpiperazine-N-2-ethanesulfonic acid) containing 100,000 counts per minute of carrier-free $Na^{125}I$. After the cells were incubated for 45 minutes at 37°C, they were washed twice with 2 ml of ice-cold buffer A, and solubilized with 1 ml of 0.1 mol/L sodium hydroxide. ^{125}I uptake was then determined by measuring the radioactivity counts per minute from each well. The doses causing a 50% decrease in iodide uptake for perchlorate, thiocyanate, and nitrate were 1.22 µmol/L (121 µg/L), 18.7 µmol/L (1086 µg/L), and 293 µmol/L (18,166 µg/L), respectively, and the relative potency of perchlorate (on a molar basis) was reported to be 15 and 240 times that of thiocyanate and nitrate. [For comparison, median serum levels of perchlorate, thiocyanate, and nitrate found in a recent study in pregnant women in New Jersey were 0.223 µg/L, 936 µg/L, 2410 µg/L, respectively (Blount *et al.,* 2009)]. It is not known how well human NIS in Chinese hamster cells simulates human NIS in human cells, how well hamster ovarian cells simulate human thyroid cells, or how well conditions in these wells simulate the complex environment of the human body.

Other unknowns regarding the Tonacchera *et al.* (2004) findings include: how the effects seen for the very high concentrations of perchlorate and the other agents used in this study correlate to effects that may be caused by lower, more common serum concentrations of these agents; how the thyroid and NIS auto-regulatory mechanisms in humans may affect relative potencies; how the fairly short-term exposures in this study correlate with the longer-term, more chronic exposures commonly seen with drinking water chemical exposures; whether or not there may be age-related or other susceptibility effects; how well the urine concentrations of each of the agents assessed correlate with the actual concentration of these agents at the NIS; what role the endogenous production of nitrate might play in affecting these relative potencies, the use of urine nitrate concentrations as an exposure metric, or auto-regulatory mechanisms; or how the presence of other agents or conditions that may inhibit the NIS, affect auto-regulatory mechanisms, or affect the thyroid in other ways might change the relative potencies reported in Tonacchera *et al.* (2004).

Gold *et al.*, 2013. In this study, serum thyroid hormone levels (fT4 and TSH) and questionnaire information on past and current doctor-diagnosed thyroid disease were collected from women who lived in an area with past perchlorate contamination. Subjects included approximately 300 women who resided near a National Priority List site in Sacramento, California, where five public drinking water wells contained between 93-250 µg/L of perchlorate. These high concentrations were thought to have begun in 1988 and ended in 1997 when the wells were capped. The study also included approximately 500 women from two neighboring comparison communities, one of which had significant airborne pollutant exposure and one of which had no noted high air or water contaminant exposure. The study did not begin, and serum thyroid hormone levels and questionnaire data were not collected, until > 4 years after the highly contaminated wells were capped. Overall, no association was found between past perchlorate exposure and thyroid hormone levels or past or current thyroid disease. The fact that thyroid hormone levels were not collected until several years after the high exposures were stopped limits the usefulness of this study since most evidence suggests that iodide uptake inhibition of perchlorate ends fairly rapidly (e.g., within a day) after the exposure is stopped (Greer *et al.,* 2002). In addition, questionnaire information on the presence of doctor-diagnosed thyroid disease is probably not a sensitive marker of the adverse effects of perchlorate exposure and its use would miss more subtle effects including the small thyroid hormone changes linked to cognitive effects in children discussed above (see pages 39-56).

Carcinogenicity

Morgan and Cassady, 2002. Morgan and Cassady (2002) assessed observed and expected numbers of new invasive cancer cases for all sites combined and 16 cancer types among residents of the greater Redlands area between 1988 and 1998. The community is known to have drinking water contaminated with perchlorate and trichloroethylene (0.09-97 ppb measured in 1980). They reported no significant differences between observed and expected numbers for all cancers, thyroid cancer, or 11 other cancer types. Significantly fewer cases were observed than expected for cancer of the lung and bronchus and the colon and rectum. More cases were observed for uterine cancer (standardized incidence ratio = 1.35; 99% CI, 1.06-1.70) and skin melanoma (standardized incidence ratio = 1.42; 99% CI, 1.13-1.77).

Li *et al.*, 2001. These authors compared the prevalence of thyroid cancer in Clark County (Las Vegas) which had measurable perchlorate concentrations in public water supplies to Washoe County, which did not. The relative risk was 0.75 (95% CI, 0.35-1.59).

Other Toxicities

Acute Toxicity

The acute lethal oral dose of perchlorate for an adult human was estimated to be 15 g, or 214 mg/kg for a 70-kg person (Von Burg, 1995).

Subchronic Toxicity

Potassium perchlorate has been used to treat Graves' disease in humans, and most of the early data on perchlorate in humans are in patients with this disease. Graves' disease is an autoimmune disorder in which patients carry immunoglobulins in their blood that bind to the TSH receptors on thyroid cells and act like TSH to stimulate DNA synthesis and cell divisions leading to a hyperthyroid state. Perchlorate inhibits the excessive synthesis and secretion of thyroid hormones by inhibiting the uptake of iodide into the thyroid and causes a discharge of accumulated iodide in the gland.

Godley and Stanbury (1954) report using potassium perchlorate to treat 24 patients with Graves' disease. Patients were treated with 600 to 1,200 mg/day for at least 11 weeks with a few patients treated for up to 52 weeks. Two patients developed gastrointestinal problems. In one patient, these effects occurred at 600 mg/day.

Crooks and Wayne (1960) administered potassium perchlorate at 600 to 1,000 mg/day to 200 patients with Graves' disease and observed one case of skin rash and three cases of nausea. In another group of 10 patients given 1,500 mg/day and 40 patients given 2,000 mg/day, five cases of skin rash, two cases of nausea, and one case of agranulocytosis occurred. Leukocyte counts returned to normal in the patient with the agranulocytosis when perchlorate treatment was stopped. The length of treatment was unclear but generally appears to have been less than 8 weeks.

Morgans and Trotter (1960) reported that three percent of 180 patients treated with 400 to 1,000 mg/day potassium perchlorate and 18 percent of 67 patients treated with 1,200 to 2,000 mg/day displayed a variety of adverse reactions that included skin rash, sore throat, gastrointestinal irritation, and lymphadenopathy. Based on the data reported by Crooks and Wayne (1960) and their own clinical observations, Morgans and Trotter (1960) recommended a daily dose of 800 mg/kg-day, a compromise between effectiveness and minimizing the toxic side effects of perchlorate.

Genetic Toxicity

No reports were found of studies that examined genetic endpoints (chromosomal aberrations, sister chromatid exchanges, etc.) in humans exposed to perchlorate.

Immunotoxicity

Weetman *et al.*, (1984) investigated the effect of perchlorate on human T and B cell responses to mitogen *in vitro.* Perchlorate at concentrations of 0, 0.01, 0.1, 1.0 and 10 mmol/L (1.17 g/L) were tested in cultures "designed to assess B and T cell responses." Supernatant immunoglobulins G and M (IgG and IgM) were measured by enzyme-linked immunoassays after culture of cells for 10 days with pokeweed mitogen. The investigators found that perchlorate at 0.1 to 10 mmol/L inhibited IgG production and at 10 mmol/L inhibited IgM production. They concluded that perchlorate has significant immunosuppressive activity at pharmacologically relevant concentrations that is not due to simple cytotoxicity (assessed by ethidium bromide/acridine orange fluorescence). However, the perchlorate concentrations in this study are in fact very high. A later study in Chinese hamster ovary cells expressing the human NIS (Ajjan *et al.*, 1998) showed perchlorate inhibition of iodide uptake evident at 0.01 micromolar, progressing to complete inhibition at 20 micromolar (0.02 mmol/L), which is much lower than the doses used in Weetman *et al.* (1984). Thus the immune effects of the high concentrations used in the study of Weetman *et al.* (1984) appear of doubtful relevance.

Hematological Effects

Graves' disease patients treated with perchlorate doses in the range of 6 to 14 mg/kg-day for three to eight months occasionally developed fatal aplastic anemia (Fawcett and Clarke, 1961; Hobson, 1961; Johnson and Moore, 1961). The mechanism of this blood disorder is not known. The use of perchlorate to treat Graves' disease was discontinued because of these cases. Nonfatal agranulocytosis was reported in patients treated with 14 mg/kg-day perchlorate for 12 days (Southwell and Randall, 1960) or three months (Sunar, 1963). Barzilai and Sheinfeld (1966) reported that 8 of 76 patients treated with 14 mg/kg-day perchlorate for at least two months developed leukopenia or other side effects. There was also one case of fatal aplastic anemia and one of fatal agranulocytosis within this group of 76 patients (Barzilai and Sheinfeld, 1966). As similar adverse hematological effects were not observed in rodents exposed to 30 mg/kg-day or 100 mg/kg-day, humans may be more sensitive than rodents for this endpoint.

5. TOXICOLOGICAL EFFECTS IN ANIMALS

The primary effect of perchlorate exposure is the disruption of thyroid hormone regulation. This mode of action is supported by the results of a number of animal studies that show that perchlorate inhibits thyroidal iodide uptake, changes serum T3, T4, and TSH levels, and subsequently causes a range of toxic effects. The animal studies, described in the section below, illustrate a range of effects that can result from the modulation of thyroid hormone regulation by perchlorate. As previously (OEHHA, 2004), human data described in earlier sections provide a reliable basis for the establishment of the PHG.

Adverse Effects on the Thyroid

Subchronic Studies of Effects of Perchlorate on the Thyroid

In many animal studies, perchlorate has been shown to perturb thyroid hormone regulation, induce hypertrophy and hyperplasia in thyroid follicular cells, and cause an increase in thyroid weight.

Shigan (1963) administered ammonium perchlorate to "white rats" at 650 mg/kg-day for one month and did not observe noticeable cumulative properties. The author also exposed "white rats" to ammonium perchlorate for three months at 190 mg/kg-day and found the treatment affected the regulation of the involuntary nervous system, caused changes in the protein fractions of the blood serum, and disrupted the liver's ability to produce glycogen for carbohydrate storage.

In a follow-up study, Shigan (1963) treated rabbits and "white rats" with 0, 0.25, 2.0, and 40 mg/kg-day of potassium perchlorate for 9 months. Many study details, such as the sex and number of animals in each dose group and the dosing medium, were not reported. In the two highest dose groups, the author found a significant increase in the amount of iodide excreted from the thyroid. It is not clear if the reported effect was seen in both species (U.S. EPA, 2002).

Caldwell *et al.* (1995) administered ammonium perchlorate to groups of Sprague-Dawley rats (six males and six females per group) in drinking water for 14 days at concentrations of 0, 1.25, 5.0, 12.5, 25, 50, 125 or 250 mg/L. The corresponding doses (male/female) in mg/kg-day are 0, 0.11/0.12, 0.44/0.47, 1.11/1.23, 2.26/3.06, 4.32/4.91, 11.44/11.47, and 22.16/24.86 mg/kg-day, respectively. At the end of the exposure period, thyroids were weighed, thyroid histopathology and morphometry examinations were performed, and thyroid hormone levels were measured with a radioimmune assay technique. The researchers reported that perchlorate exposure decreased circulating T3 and T4 and increased serum TSH. There is also evidence that rT3 (formed mostly in extrathyroidal tissues) and thyroglobulin levels were also increased. They also found that perchlorate exposure was associated with decreases in thyroid gland follicular lumen size and increases in relative thyroid weights. At the lowest

dose, 0.1 mg/kg-day, statistically significant changes in serum T4 were observed in both sexes; this level can be identified as a LOAEL.

Springborn Laboratories (1998) administered ammonium perchlorate via drinking water to male and female Sprague-Dawley rats (10 rats/sex/dose) at doses of 0, 0.01, 0.05, 0.2, 1.0, and 10 mg/kg-day for 14 and 90 days. An additional 10 rats/sex/dose were sacrificed after a 30-day recovery period following cessation of the 90-day exposure at doses of 0, 0.05, 1.0, and 10 mg/kg-day, to evaluate reversibility of any observed lesions. No statistically significant toxicological findings were observed among the groups with respect to clinical observations, body weights, food or water consumption, ophthalmology, hematology, or clinical chemistry. The researchers reported perchlorate exposure was associated with increased thyroid weights, thyroid follicular cell hypertrophy, and thyroid colloid depletion. Mean thyroid weights of male rats in the highest dose group were significantly increased after 14 and 90 days of exposure, while mean thyroid weights of female rats in the highest dose group were significantly increased after 90 days of exposure. No thyroid pathology was observed in other dose groups. After a 90-day exposure period followed by a 30-day recovery period, there was no increase in thyroid weight in either male or female rats in the 0.05, 1.0, and 10 mg/kg-day dose groups (Siglin *et al.*, 2000).

After 14 days of exposure, mean serum TSH levels were significantly increased in males at 0.2 mg/kg-day and higher, and in females at 0.05 mg/kg-day and higher, compared with the controls. Mean serum T4 levels were significantly decreased in both sexes at 10 mg/kg-day. Mean serum T3 levels were significantly decreased in males at levels of 0.01 mg/kg-day and higher. No statistically significant differences in T3 levels were observed in the female treatment groups.

After 90 days of treatment, mean TSH levels were significantly increased in males at 0.2 mg/kg-day and higher, and in females at 10 mg/kg-day only. Mean T3 and T4 levels were significantly decreased in both sexes at 0.01 mg/kg-day and higher. Based on this data set, a LOAEL of 0.01 mg/kg-day can be identified.

Following a 90-day exposure period and a 30-day recovery period, TSH levels were significantly increased in all three female recovery groups (0.05, 1.0, and 10 mg/kg-day), whereas no significant differences in TSH levels were observed in the male recovery groups. Mean T4 levels were significantly lowered in all three male recovery groups (0.05, 1.0, and 10 mg/kg-day), whereas no significant differences in T4 levels were observed in the female groups. Mean T3 level was significantly lower in females at 10 mg/kg-day. No statistically significant differences in T3 levels were observed in the male recovery groups (Siglin *et al.*, 2000). The authors did not speculate on the differences between the male and female data.

Siglin *et al.* (2000) noted there was a change in the mean TSH levels in the male and female control groups between 14 days and 120 days. They also found changes in mean T3 levels of control females over the course of the study. It was not clear if the observed variability in mean control hormone levels was reflective of normal age-related variations or due to other factors such as the relatively small sample sizes.

Studies of Perchlorate's Inhibitory Effects on Iodide Uptake by the Thyroid

The previous and subsequent section describes various studies that have documented the effects of perchlorate on thyroid and pituitary hormones as well as the thyroid of the treated animals. This section describes animal studies of perchlorate's effects on thyroidal iodide update.

Yu *et al.* (2000), working with the United States Air Force and U.S. EPA, investigated the inhibitory effects of perchlorate on thyroidal iodide uptake in rats. They injected perchlorate at 0, 0.01, 0.1, 1 or 3 mg/kg into groups of male Sprague-Dawley rats (six animals per dose and time point). At two hours post dosing, the rats were challenged with ^{125}I with carrier (33 μg/kg) by intravenous injection and euthanized at various time points post-dosing. Statistically significant thyroidal iodide uptake inhibition was found in the 1 and 3 mg/kg perchlorate dose groups at the 2, 6, and 9 hour time points. In addition, significant inhibition was also observed in the 0.1 mg/kg dose group at the 9 hour time point (Table 43).

Table 43. Percent Inhibition of Iodide Uptake in the Thyroid Gland of Male Rats (n=6) Dosed with Perchlorate (Yu *et al.*, 2000)

Time points	Perchlorate dose (mg/kg)	Mean iodide concentration in the thyroid (µg/g)	Thyroidal iodide uptake inhibition (%)[a]
2 hours	Control[b]	24.4	-
	0.01	21.3	13
	0.1	18.6	24
	1	7.4[c]	70
	3	3.0[c]	88
6 hours	Control[b]	46.5	-
	0.01	36.7	21
	0.1	32.0	31
	1	19.2[a]	59
	3	9.1[a]	80
9 hours	Control[b]	55.0	-
	0.01	49.2	11
	0.1[c]	39.2	29
	1	24.7[c]	55
	3	10.0[c]	82

[a]Percent inhibition = (control mean – dose mean) x 100 / (control mean)
[b]Dosed with ^{125}I with carrier only (33 µg/kg)
[c]$p<0.05$ compared to controls.

In a follow-up study, Yu *et al.* (2000) exposed groups of male Sprague-Dawley rats (6 animals per dose and exposure duration) to perchlorate in drinking water with target concentrations of 0, 1, 3, and 10 mg/kg-day continually for 1, 5, or 14 days. At the end of day 1, 5, or 14, rats were challenged once with 33 µg/kg ^{125}I with carrier and euthanized two hours later. Blood and thyroid gland were collected for analyses. A dose-related inhibition was noted in the one-day treatment group. The degree of inhibition was reduced over time and by exposure day 14, no inhibitory effect was observed in the 1 and 3 mg/kg-day groups. In a similar study, thyroid hormone profile of rats exposed to perchlorate was investigated. Male rats in groups of 8 were exposed to perchlorate in drinking water at 0, 0.1, 1, 3, and 10 mg/kg-day continually for 1, 5, or 14 days. In all treated groups, regardless of dose or exposure duration, TSH levels were increased compared to the control. The serum T4 levels were initially decreased in all dose groups except the lowest, 0.1 mg/kg-day. By 14 days, the 1 mg/kg-day dose group returned to control T4 values while T4 levels of the 3 and 10 mg/kg-day dose groups were still significantly depressed.

Yu *et al.* (2002) modeled the effects of perchlorate on the hypothalamus-pituitary-thyroid axis in the male rat. They found a high correlation between serum concentrations of perchlorate and percentage inhibition in thyroidal iodide uptake, irrespective of the route of administration. They found the hypothalamus-pituitary-thyroid axis responded quickly to perchlorate's blocking effects on thyroidal iodide uptake. Serum thyroid hormone levels decreased and serum TSH levels increased in response to perchlorate. Under the influence of TSH, the thyroid was up-regulated and was able to overcome the blocking effects of perchlorate by increasing its capacity to sequester iodide and produce hormones. Yu *et al.* (2002) noted that this is a dose-dependent phenomenon, which was overwhelmed by the blocking effects of high serum levels of perchlorate (corresponding to above approximately 1 mg/kg-day).

In Paulus *et al.* (2007), perchlorate-induced inhibition of thyroidal iodide uptake was measured in normally fed female Sprague-Dawley rats and in rats made iodine-deficient by long-term restriction of iodine in the diet (n = 10 rats per perchlorate-iodine group). In the iodine deficient animals, dietary iodine levels were 9-10 times lower than those in the normally fed animals. T4 levels in the iodine-deficient animals were 50 percent lower than in the normally fed animals, although TSH levels did not differ across the diet groups. Both groups were given a dose of ^{131}I via gavage, and ^{131}I uptake was measured in the thyroid. The proportion of administered ^{131}I taken up by the thyroid was greater in the iodine deficient rats than in the rats fed a normal diet.

Rats from each diet group were then given either no perchlorate or perchlorate at doses of 1.1, 5.6, or 28 mg/L, and percent of radioactive iodide uptake (%RAIU) was re-measured. In the normally fed rats, perchlorate produced significant inhibition of %RAIU at every dose group. In the iodine-deficient rats, %RAIU was decreased at all dose levels except the lowest dose of 1.1 mg/L (Figure 10), although the %RAIU reduction in the second highest dose group was not statistically significant. These results suggest that iodine-deficient animals are resistant to the iodide-uptake inhibiting effect of perchlorate compared to animals with adequate iodine intake. Based on this, the authors concluded that if the human NIS system reacts to iodine deficiency in a manner similar to the rodents in this study, iodine-deficient individuals may not represent a sensitive subpopulation for perchlorate toxicity. Importantly, this conclusion is based on a lack of findings in only one dose group. In addition, it is currently unknown whether these results apply to humans. Finally, the degree of iodine deficiency induced in the iodine deficient rats was fairly severe (the dietary iodine levels were one tenth of what they were in the normally fed animals). It is not known whether the effects seen in rats with this severe degree of iodine deficiency are relevant to the more moderate iodine deficiencies that are common in human populations.

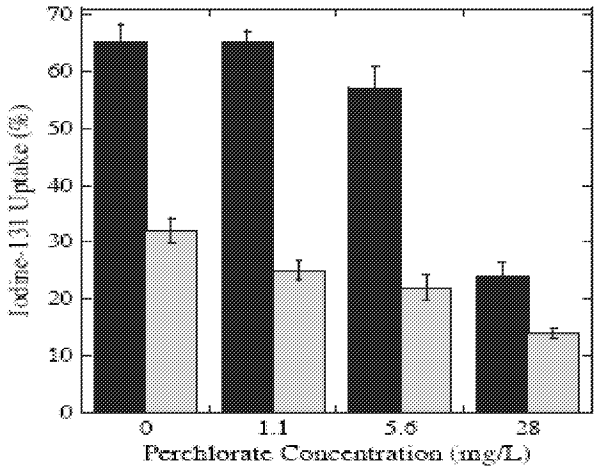

Figure 10. Dose-Response Relationship between Perchlorate and Radioactive Iodide Uptake in the Thyroid in Rats with Normal and Low Iodine Intake (Paulus *et al.*, 2007). Gray bars are values from rats fed a normal diet, black bars are values from rats fed a low-iodine diet. Values shown are mean ± SEM.

Clewell *et al.* (2001; 2003; 2007) have developed and attempted to validate rat and human physiologically-based pharmacokinetic (PBPK) models for the estimation of the effect of life stage and species on perchlorate and iodide inhibition kinetics. The models have been used to estimate perchlorate distribution in the male, pregnant, fetal, lactating and neonatal rat, and predict resulting inhibitory effects on thyroidal iodide uptake. The authors conclude that the fetal rat thyroid is most vulnerable to inhibition. Clewell *et al.* (2007) reported that "the fetus is predicted to receive the greatest dose (per kilogram body weight) due to several factors, including placental sodium-iodide symporter (NIS) activity and reduced maternal clearance of ClO_4^-."

Developmental and Reproductive Toxicity

A number of toxicity studies have shown that perchlorate exposure causes a variety of adverse health effects in the offspring of the test animals.

Developmental Toxicity

Postel (1957) gave a one percent solution of potassium perchlorate to eleven guinea pigs in the second or third week of pregnancy. The control group consisted of three sows receiving a diet containing 0.48 µg/g of iodine, distilled water *ad libitum*, and 50 mg of ascorbic acid orally twice a week. The treated sows were divided into four groups which received 0, 8, 16, or 32 µg, respectively, of triiodothyronine (T3) by subcutaneous injection each day. Control sows and those receiving potassium perchlorate alone were given daily injections of saline solution. The overall mean dose of potassium perchlorate

was 1,520 mg/kg-day in the T3-injected sows and 740 mg/kg-day in the group receiving only potassium perchlorate. The mean exposure duration was 37 days (range 21-48 days). One hour before the removal of the fetuses, radioactive sodium iodide was injected subcutaneously into the sow. Radioactivity of the blood and thyroids of the sows and fetuses were analyzed.

Postel reported that massive enlargement of the fetal thyroid was observed in all the perchlorate treated groups, with or without T3 injection. The overall mean weight was 491 mg/100 g body weight, compared with a mean control fetal thyroid weight of 32 mg/100 g body weight. Perchlorate did not cause enlargement of the maternal thyroid in any of the treatment groups, with or without T3 injection.

Postel (1957) also reported that the thyroid/serum radioiodide concentration ratio was approximately 175 in fetuses and 50 in sows in the control group. It was suggested that this finding supports the concept that the normal fetal thyroid is in a relatively hyperplastic state. The thyroid/serum radioiodide concentration ratios of both the perchlorate-treated sows and their fetuses were significantly lower than those of the controls.

Lampe *et al.* (1967) gave perchlorate-treated food to 12 rabbits from the beginning of pregnancy through gestation day 21 or 28. The rabbits were dosed at 100 mg/kg-day. No concurrent controls were used. Ingestion of perchlorate was found to cause an increase in maternal and fetal thyroid weights. On the 21st day of treatment, the maternal thyroid weights in treated animals were nearly three times higher than control thyroids; fetal thyroids from the treated animals were nearly four times the control weights. Continued intake of perchlorate further enhanced the increase in thyroid weight, particularly in the fetus. On the 28th day of treatment, the maternal thyroid weights in treated animals were nearly four times higher than control thyroid weights, and fetal thyroid weights from treated animals were nearly nine times higher than control thyroid weights.

Sztanyik and Turai (1988) investigated the safety of using potassium perchlorate or potassium iodide as blocking agents to prevent the uptake of radioiodine by fetuses. They injected these compounds into pregnant albino rats (body weight 200 to 250 grams) in amounts sufficient to "significantly decrease" uptake of radioiodine by the fetuses (0.1 to 6.0 mg potassium perchlorate per adult rat). There was no evidence of embryo- or fetotoxicity at these doses. In summary, the results of this study, and those of Postel (1957) and Lampe *et al.* (1967), all provide evidence that perchlorate can pass through the placenta from the mother to the fetus and affect the fetal thyroid in test animals.

A developmental neurotoxicity study of ammonium perchlorate in rats was conducted by Argus Research Laboratories (1998a; 1998b; 1998c). Ammonium perchlorate was administered to groups of 25 female Sprague-Dawley rats via drinking water at target doses of 0, 0.1, 1.0, 3.0, and 10 mg/kg-day. The dosing period was from the beginning of gestation (GD 0) to postnatal day (PND) 22.

Five dams per group were selected for sacrifice and blood collection on PND 10. Pups (F1 generation) were counted and clinical signs recorded daily during pre- and post-weaning. Some of the pups were assigned to four different subsets for additional evaluations: Subset 1 for brain weight and neurohistological examination on PND 12; Subset 2 for passive avoidance testing, water maze testing, and blood collection for thyroid and pituitary hormone analysis; Subset 3 for motor activity evaluation and auditory startle habituation; Subset 4 for regional brain weight evaluation and neurohistological examination on PNDs 82 to 85. U.S. EPA (2002) analyzed the F1 data and concluded that perchlorate treatment was associated with: (a) brain morphometric changes in the 10 mg/kg-day dose group and possibly also the 3 mg/kg-day dose group; (b) thyroid colloid depletion, hypertrophy, and hyperplasia in the 0.1 and 3 mg/kg-day dose groups; (c) thyroid hormone (T3 and T4) changes in the 0.1 and 1 mg/kg-day dose groups; and (d) increases in motor activity in some dosed animals.

Argus Research Laboratories (1999; York *et al.*, 2001) reported a two-generation reproductive toxicity study in Sprague-Dawley rats. Male and female rats (30 rats/sex/group) of the first generation (P) were exposed to ammonium perchlorate in drinking water at 0, 0.3, 3, and 30 mg/kg-day. One male and one female were allowed a cohabitation period of a maximum of 14 days. Lactation day (LD)1, postpartum, was defined as the day of birth. Rats that did not deliver a litter were sacrificed on gestation day 25 and examined for pregnancy status. At the end of the 21-day postpartum period, all surviving P rats were sacrificed. Pups not selected for continued evaluation were also sacrificed on LD 21. The selected F1 pups were dosed during the post weaning, cohabitation, and lactation periods. All F1 generation dams and their litters (F2 generation) were sacrificed on LD 21. York *et al.* (2001) reported that perchlorate is not a reproductive toxicant in the doses tested. In both the P and F1 adult rats, there were no deaths, abortions, or premature deliveries. No changes were reported in any sperm parameters in either P or F1 adult male rats nor on mating or fertility parameters in either P or F1 adult female rats (estrous cyclicity, fertility index, number of days in cohabitation, and number of rats mated). Natural delivery and litter observations for both F1 and F2 generation pups were comparable among the treated and control groups. Treatment-related effects were not observed on the gestation index, the number of dams delivering litters, the duration of gestation, the average number of implantations, the average number of live pups, the viability and lactation indices, the sex ratios, or the pup body weights.

York *et al.* (2001) found that perchlorate exposure caused statistically significant, dose-dependent changes in thyroid weight, histopathology, and hormone levels in P, F1, and F2 generation rats. Relative thyroid weights were significantly increased in the 30 mg/kg-day dose group for both sexes in the P generation and for F2 generation pups. However, in the F1 generation adult rats, relative thyroid weights were significantly increased in all dose groups for females and in the 3 and 30 mg/kg-day dose groups for male rats. All three generations developed hypertrophy and hyperplasia of thyroid follicular epithelium that increased in incidence and severity in a dose-related manner. Dose-related changes in TSH,

T3, and T4 were also observed in the treated rats. However, these changes were inconsistent among the different generations, sexes, and ages of animals.

U.S. EPA (2002) noted that two male rats from the high dose group (30 mg/kg-day) in the F1 generation (second parental generation) in the study had adenomas of the thyroid. These males were dosed from conception to 19 weeks of age. Without incorporating historical data, the difference between 0/30 in the control and 2/30 in the 30 mg/kg-day is not statistically significant by standard tests (e.g., Fisher's exact). However, using two earlier reported background incidence rates of 3.6 percent and 3.9 percent for thyroid follicular cell adenomas in male Sprague-Dawley rats in 2-year studies and Bayesian analysis, U.S. EPA (2002) determined the increase in thyroid follicular cell adenoma at 19 weeks in male Sprague-Dawley rats exposed to 30 mg/kg-day to be statistically significant.

Effects of perchlorate on motor activity in Sprague-Dawley rats were studied by Bekkedal *et al*. (2000). The females were dosed with ammonium perchlorate in drinking water for two weeks at 0, 0.1, 1, 3, or 10 mg/kg-day prior to mating with the breeder males and through PND 10. As dosing was stopped on PND 10, it is likely that the pups were not directly exposed to perchlorate in drinking water. On PND 14, one male and one female were randomly selected from each litter to be used in the motor activity testing. These same animals were tested on PND 14, PND 18, and PND 22. Pups were individually tested in automated Opto-Varimex Activity boxes where 9 different measures of activity were recorded for 90 minutes on each test day. Data were analyzed in 9, 10-minute blocks using a repeated measures ANOVA.

Bekkedal *et al*. (2000) reported no statistically significant differences for any of the nine measures of motor activity, and there were no reliable interactions related to treatment. A general pattern in the results was noticed. The authors suggested that there was a divergence in activity between the control and treated groups which emerged late in the 90-minute testing sessions.

U.S. EPA and NIEHS used a Bayesian hierarchical model to analyze the motor activity data reported by Argus Research Laboratories (1998a) and Bekkedal *et al*. (2000). They built a linear mixed-effects regression model relating dose, sex, age, habituation time and a habituation time × dose interaction term to the expected number of ambulatory movements, with an animal-specific intercept included to account for within-animal dependency (U.S. EPA, 2002). U.S. EPA concluded that there was evidence of an increasing dose-response trend in motor activity in both data sets, and suggested that the lower limit on the estimated dose corresponding to a 10 percent increase in motor activity relative to control can be used as a surrogate for the NOAEL. Because of the variability in the Argus Research Laboratories (1998a) study, a NOAEL that relied on the Bekkedal *et al*. (2000) study was chosen at 1 mg/kg-day to represent effects on motor activity from these combined data.

Argus Research Laboratories (2001) studied the effects of perchlorate on thyroid and brain development both during gestation and postnatally. Perchlorate was administered in drinking water to female rats two weeks prior to cohabitation at 0, 0.01, 0.1, 1, or 30 mg/kg-day and continued through the day of sacrifice. F1 generation rats were not directly dosed but might have been exposed *in utero* during gestation and via maternal milk and maternal water during the postpartum period. The rats were selected only from female rats that had litters of at least 12 live offspring at the time of cesarean-sectioning (Part A) or at the time of the first tissue collection (Parts B and C). P generation rats assigned to Parts B and C that delivered a litter were sacrificed on either PND 9 (Part B) or PND 21 (Part C). The thyroid and brain from one male and one female pup per litter were selected for histological and morphometric evaluation, with one set evaluated on PND 4, PND 9, and PND 21. Details of the study and findings are described in the study report prepared by the Argus Research Laboratories (2001), and a summary of the findings and evaluations is provided below.

According to the report, there were no deaths, adverse clinical observations or necropsy findings during the premating, gestational and/or lactation periods that were treatment-related in Parts A, B, and C. There were 16 pregnant dams in Part A. No treatment-related changes were found in cesarean-sectioning or litter parameters. There were 15 or 16 pregnant dams for Parts B and C that delivered. Natural delivery was unaffected by the treatment and all clinical and necropsy observations in the F1 generation pups were considered unrelated to the treatment.

The absolute and relative thyroid weights of dams at the highest dose were increased. The absolute thyroid weights of some pups exposed at 1 and 30 mg/kg-day were increased. Furthermore, the absolute thyroid weights of the PND 9 male pups in the 0.01, 0.1, 1 and 30 mg/kg-day dose groups were significantly increased over the controls.

An exposure-related increase in the incidence and severity of decreased colloid was noted in dams in the 1 or 30 mg/kg-day groups. Similar observations were made on the fetuses at birth and pups at PND 4 and PND 9. An increased incidence of follicular cell hypertrophy and/or hyperplasia was found in dams in the 30 mg/kg-day dose group. An increased incidence of follicular cell hyperplasia was also found in the 1 mg/kg-day dams sacrificed on PND 21.

In Part A, maternal TSH levels were significantly increased and T4 levels were significantly decreased at all exposure levels. Fetal TSH levels were significantly increased at 1 and 30 mg/kg-day while T3 was significantly decreased at all exposure levels. Changes of both the maternal and fetal thyroid hormone levels occurred in an exposure-dependent manner.

Maternal and fetal thyroid and pituitary hormone levels were also affected by various doses of perchlorate in Parts B and C. Most changes occurred in an exposure-dependent manner. In the PND 21 male pups, TSH levels were

significantly increased and T4 levels were significantly decreased at all exposure levels. T3 levels were also significantly decreased in the 1 and 30 mg/kg-day groups. In the PND 21 female pups, TSH levels were increased at all exposure levels, reaching statistical significance in the 0.1, 1, and 30 mg/kg-day groups. T4 levels were decreased with increased exposure but did not reach statistical significance.

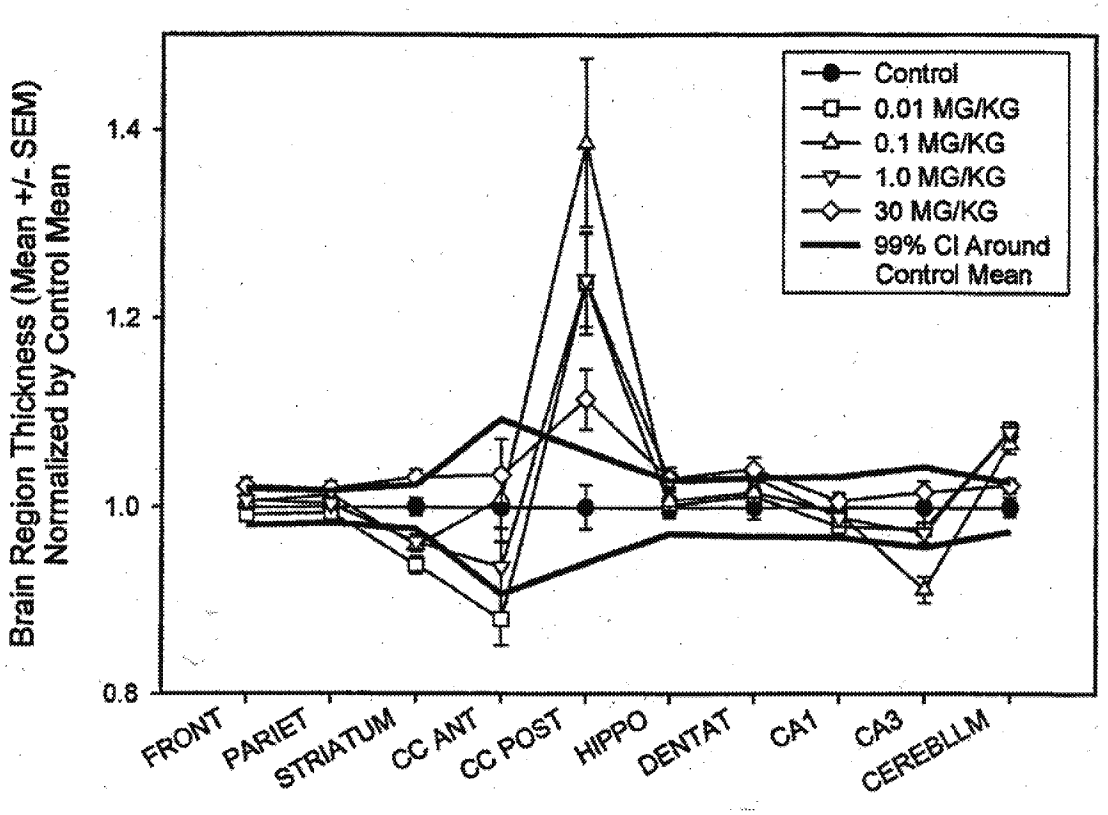

Figure 11. Profile Analysis of Brain Morphometry Measurements for PND 21 Rat Pup Brain Regions. The male and female linear thickness measurements were combined and normalized by the control mean of each region. The control data are represented by the horizontal line at 1.0. Profile analysis determines whether the vectors of measurements from each treatment group differ from each other and control in a dose-dependent fashion. The heavy line represents the ±99 percent confidence interval around the mean control values. Note that while this plot uses the normalized data to more easily illustrate the data vectors, the actual analysis was performed using raw data values (from U.S. EPA, 2002).

Size of various brain areas was also measured in brain sections from the PND 9 and PND 21 pups. Due to signs of disruption or damage found in the PND 9 sections that might have compromised the measurements, U.S. EPA (2002) relied upon the PND 21 measurements. In the PND 21 brains, the striatum, cerebellum, and corpus callosum in the exposed animals all showed significant differences from those of controls with the lowest administered dose of ammonium perchlorate, 0.01 mg/kg-day. As shown in Figure 11, different brain

regions show an inverted U or U-shape dose response. For instance, the corpus callosum showed a notable increase in linear extent of 24 percent or more at PND 21 in the 0.01, 0.1, and 1 mg/kg-day dose groups; however, this effect was not observed at the highest dose group, 30 mg/kg-day. Using these data, U.S. EPA (2002) identified a LOAEL of 0.01 mg/kg-day for the adverse effects of ammonium perchlorate on the developing brain in rats. This is equivalent to 0.0085 mg/kg-day for the perchlorate anion alone.

Thuett *et al.* (2002) studied the effects of *in utero* and lactational exposure to ammonium perchlorate on developing deer mice. Breeding pairs were dosed continuously with 0, 1 nM, 1 µM, or 1 mM of ammonium perchlorate in drinking water, from cohabitation until pups were sacrificed at PND 21. Pups from the second litter were used for evaluation. The researchers found the treated groups tended to have smaller litter sizes than did controls, but a greater survival percentage. They reported that perchlorate is a developmental toxicant and showed variable effects with increasing concentrations. Body weights of the pups in the 1 µM group were consistently lower than in the controls and in other treatments after PND1. They also reported that perchlorate treatment had an effect on the liver and heart weights. However, although liver weight alone was statistically different between treatments, liver weight when analyzed with body weight as a covariate showed no statistically significant difference. Heart weights for male pups were decreased in the 1 µM and 1 mM treatment groups. Heart weights decreased while body weight was increasing. Citing other study results, Thuett *et al.* (2002) suggested that an inadequate level of thyroid hormones during cardiac muscle development can alter cardiac function and/or heart size.

Reproductive Toxicity

Female rats were dosed with perchlorate in drinking water during gestation. The daily intake rates were estimated to range from 237 mg/rat to 615 mg/rat (Brown-Grant, 1966; Brown-Grant and Sherwood, 1971, as cited in U.S. EPA, 2002). These researchers observed no significant differences in litter size, number of pups, and pregnancy rate. Relative thyroid weights of the dams and litters were increased significantly compared with the controls.

A developmental toxicity study was performed on New Zealand White rabbits (Argus Research Laboratories, 1998d). It involved 25 naturally-mated does per group exposed to ammonium perchlorate in drinking water at 0, 0.1, 1.0, 10, 30, and 100 mg/kg-day from gestation day 6 to gestation day 28. Observations were based on 22, 24, 23, 24, 24, and 23 pregnant does that survived to gestation day 29 in the 0, 0.1, 1, 10, 30, and 100 mg/kg-day dosage groups, respectively. Fetuses were delivered by cesarean section. The authors reported that doses as high as 100 mg/kg-day did not affect litter parameters. All values were within the historical ranges of the testing facility. The litter averages for corpora lutea, implantations, litter sizes, live and dead fetuses, early and late resorptions, percent dead or resorbed conceptuses, percent male fetuses and fetal body weights were comparable and did not differ significantly in the six dosage groups.

All placentas appeared normal and no doe had a litter consisting of only resorbed conceptuses (Argus Research Laboratories, 1998d). U.S. EPA (2002) analyzed the maternal hormone data and noted statistically significant decreases in T4 for the 1, 10, 30, and 100 mg/kg-day dose groups. There were no statistically significant changes in T3 or TSH at any dose.

Argus Research Laboratories (1998d) also reported that no fetal alterations (defined as malformations and variations) were attributable to exposure to ammonium perchlorate at doses as high as 100 mg/kg-day: (a) the incidences were not dosage-dependent; (b) the observation occurred in only one or two high dosage group fetuses; or (c) the incidences were within the averages observed historically at the testing facility.

OEHHA notes that rabbit is probably not an appropriate animal model for the study of adverse developmental effects of perchlorate. Studies have shown that the placental iodide transport in rabbit is capable of generating a fetal serum-to-maternal serum iodide concentration of 5/1 to 9/1, thus facilitating the production of fetal thyroid hormone. A similar transport mechanism is not known to exist in human placenta (Hall and Myant, 1956 and Roti *et al.*, 1983, as cited in Fisher, 1996).

In a study by Argus Research Laboratories (2000), female rats were dosed at 0, 0.01, 0.1, 1.0 and 30.0 mg/kg-day ammonium perchlorate in drinking water beginning 15 days before cohabitation and continuing through the day of sacrifice. All rats were sacrificed on gestation day 21, and a gross necropsy of the thoracic, abdominal, and pelvic viscera was performed. Preimplantation loss was noted at all dose levels: 12, 18, 20, 16, and 25 percent at the respective doses from 0 to 30 mg/kg-day. U.S. EPA (2002) noted that it was not clear whether these increases were statistically or biologically significant compared to control animals. OEHHA analyzed the data by the Mann-Whitney U test (since the data are not normally distributed) and found that the increase in preimplantation loss was statistically significant in the 30 mg/kg-day group compared to controls ($p<0.05$). A decrease in the number of live fetuses was also reported to be statistically significant ($p<0.05$) at 30 mg/kg-day, although no significant decrease was noted in the lower dose groups. Ossification sites per litter for sternal centers and forelimb phalanges were significantly reduced at 30 mg/kg-day.

Carcinogenicity

A number of animal studies have been reported that may be useful in determining the carcinogenic potential of perchlorate. However, the interpretation of the study results is hampered by the small number of animals per dose group, short exposure and observation durations, lack of multiple dose groups, and co-exposure to other cancer causing agents.

Gauss (1972) treated female NMRI mice with one percent potassium perchlorate in the diet or the control diet for 160 days. The one percent dose is equivalent to approximately 2,000 mg/kg-day based on standard assumptions. The investigator noted progressive changes in the thyroids of treated mice beginning with colloid loss, progressing to increases in size of nuclei and increased epithelial height, followed by appearance of hyperplasia and hypertrophy of the thyroid parenchyma. Later in the treatment period, hyperplastic follicles, areas of adenomatous tissue, adenoma complexes and secreting cystadenomas were observed. No progression to malignancy was observed during the study period.

Several Japanese investigators (Hiasa *et al.*, 1987) tested potassium perchlorate for its ability to promote the carcinogenic activity of N-bis(2-hydroxypropyl)nitrosamine (DHPN). They divided the rats into four groups. Groups 1, 2, and 3 received 1,000 ppm potassium perchlorate, 1,000 ppm potassium iodide, or 1,000 ppm propylthiouracil in the diet, respectively. Group 4 was the control and received the basal diet throughout the study period of 18 weeks. At the beginning of the study, 50 percent of the rats in each group were injected with DHPN at 280 mg/100 g body weight as an initiator. Rats treated with both chemicals had a 100 percent incidence (20/20) of thyroid adenomas. Rats treated with potassium perchlorate alone had no thyroid adenomas. The incidence was five percent (1/20) in rats given DHPN alone. The investigators concluded that potassium perchlorate promoted the development of thyroid tumors in the rats treated with DHPN, but the chemical itself was not carcinogenic in this experiment.

Groups of male Wistar rats were exposed for two years to zero or one percent potassium perchlorate in their drinking water (Kessler and Kruskemper, 1966). Based on body weights and estimated water consumption, the one percent concentration was estimated to provide a dose of approximately 1,300 mg/kg-day. Animals were sacrificed and examined after 0, 40, 120, 220 and 730 days of exposure. Body weights of control and exposed animals were similar throughout the experiment, but thyroid weights of the exposed rats increased markedly compared to control rats at each examination interval. At 40 days, the exposed rats showed follicular cell hyperplasia, i.e., small follicles with high epithelia, large nuclei, numerous mitoses, colloid resorption and low-grade mesenchymal reaction. According to the authors, these changes are typical of thyroid glands stimulated by TSH for a relatively short time. Diffuse degenerative changes with fibrosis and increased colloid were observed after 200 days. Four of 11 rats treated with one percent potassium perchlorate for two years developed benign thyroid tumors. The twenty untreated controls had no thyroid tumors.

Pajer and Kalisnik (1991) divided 72 female BALB/c mice into 6 groups. Three groups were given 1.2 percent sodium perchlorate in drinking water, while three groups were controls. Eight or 32 weeks after the beginning of the study, one perchlorate and one control group of animals were irradiated with a total of four Grays of ionizing radiation (gamma rays) over a period of five days. Forty-six

weeks after the beginning of the experiment, 42 animals were sacrificed, while 30 had died during the experiment. The perchlorate dose to the treated mice was about 2,100 mg/kg-day based on standard assumptions for body weight and water consumption. Perchlorate treatment alone caused hypothyroidism with hypertrophic and hyperplastic thyroid epithelial cells as well as pituitary thyrotropic cells. Perchlorate and irradiation together caused effects similar to those caused by perchlorate treatment alone. Follicular cell carcinomas of the thyroid gland were found after perchlorate treatment (5/6 mice) and after perchlorate with irradiation (14/14), both statistically significant at $p<0.001$ versus controls (0/22).

The data indicate perchlorate caused thyroid follicular cell carcinomas in the treated mice. The study result is limited by the small number of animals in the perchlorate-only treated group, the design of the study, and the deaths of over 40 percent of the mice before the end of the experiment.

In a two-generation reproductive toxicity study in rats (Argus Research Laboratory, 1998b), two out of 30 male Sprague-Dawley rats (P2) in the highest dose group (30 mg/kg-day) were found to have adenomas of the thyroid. No such tumors were found in the control group or the other dosed groups (0.3 mg/kg-day and 3 mg/kg-day). In the study, the male rats were exposed to ammonium perchlorate in drinking water from conception to 19 weeks of age. As thyroid follicular cell adenomas are relatively rare in male Sprague-Dawley rats (the background incidence of this tumor reported in the literature was only 3.6-3.9 percent), U.S. EPA (2002) concluded that the increase in tumor incidence was treatment related.

In a number of subchronic perchlorate studies, increased thyroid follicular cell hypertrophy and hyperplasia were observed in some of the treated animals (Lampe *et al.*, 1967; Caldwell *et al.*, 1995; Springborn Laboratories, 1998; Argus Research Laboratories, 1998a, 1999, 2001; Keil *et al.*, 1998). Summaries of these studies are provided in sections above. The data indicate that oral administration of perchlorate induces hyperplasia in the thyroid of rodents and if the exposures are lengthened, some of the lesions might progress to thyroid tumors.

Other Toxicities

Acute Toxicity

In acute toxicity testing, animals generally died within the first few days after oral administration of high doses of ammonium perchlorate (750 to 4,200 mg/kg). Autopsy findings included necrosis and hemorrhaging of the mucous membranes of the stomach. Intestinal damage, pulmonary edema, and vascular dilation and congestion of the spleen, brain and sinuses were also noted (Von Burg, 1995).

Table 44, showing acute LD_{50} values for perchlorate salts in several species, is modified from Von Burg (1995), compiled from Schilt (1979), U.S. EPA (1971), Shigan (1963), and Joesten and Hill (1966). The lethal dose for the various perchlorate salts when administered to mice by intraperitoneal injection varied over a 50-fold range.

Mannisto *et al.* (1979) administered potassium perchlorate to male Sprague-Dawley rats in drinking water for four days at concentrations of 0, 10, 50, 100 or 500 mg/L. At the end of the exposure period, they measured blood levels of TSH and thyroid hormones (T3 and T4). Significant changes (increased TSH and decreased T3 and T4) were observed in the 100 and 500 mg/L (15.3 and 76.3 mg/kg-day) exposure groups. In the 50 mg/L (7.6 mg/kg-day) exposure group, there was a significant decrease in concentration of T3 and T4; the TSH level was increased, but the increase was not statistically significant.

Table 44. Acute LD_{50} Values for Perchlorate Salts (Modified from Von Burg, 1995; Schilt, 1979; U.S. EPA, 1971; Shigan, 1963; Joesten and Hill, 1966)

Species	Route of Administration	Cation	Dose (mg/kg)
Rat	Oral	NH_4^+	3,500 to 4,200
Mouse	Oral	NH_4^+	1,900 to 2,000
Rabbit	Oral	NH_4^+	750 to 1,900
Guinea Pig	Oral	NH_4^+	3,310
Mouse	i.p.	Li^+	1,160
Mouse	i.p.	Mg^{++}	1,500
Mouse	i.p.	Na^+	1,150
Mouse	i.p.	Mn^{++}	410
Mouse	i.p.	Fe^{+++}	370
Mouse	i.p.	Co^{++}	160
Mouse	i.p.	Ni^{++}	100
Mouse	i.p.	Cu^{++}	29
Mouse	i.p.	Zn^{++}	76

Genetic Toxicity

Ammonium perchlorate was tested in a battery of genotoxicity tests, and found to be negative in all tests (U.S. EPA, 2002). Ammonium perchlorate was negative in the reverse mutation assay in *Salmonella typhimurium* (TA98, TA100, TA1535, TA1537) with and without S9 activation (ManTech Environmental Technology, 1998). The Ames tests were later repeated by the National Institute of

Environmental Health Sciences. Strains TA102 and TA104 were added to cover the possibility that ammonium perchlorate causes mutation by producing reactive oxygen species or other DNA damaging radicals. The repeat tests also used the pre-incubation test methodology as it provides better contact between the test material and the target organism. Ammonium perchlorate was negative in the reverse mutation assay in *S. typhimurium* (TA98, TA100, TA1535, TA97, TA102, and TA104) with and without S9 activation, thus confirming the original Ames test results (Zeiger, 1998).

Ammonium perchlorate was negative in the L5178Y/TK$^{+/-}$ mouse lymphoma assay without S9 activation. Results of the mouse lymphoma assay with S9 activation were equivocal because of low frequency of mutations in the positive controls (ManTech Environmental Technology, 1998). The test was later repeated. In this assay, concentrations of ammonium perchlorate in the treatment medium of 50 to 5,000 µg/mL were negative in the L5178Y/TK$^{+/-}$ mouse lymphoma mutagenesis assay in the absence and presence of Arochlor-induced rat liver S9 (BioReliance, 1999). The results of the repeat study provided support for the negative results reported in the first study.

Ammonium perchlorate tested negative in *in vivo* micronuclei assays in mice and rats. In the mouse micronucleus assay, five male and five female Swiss CD-1 mice were dosed by gavage at 0, 62.5, 125, 250, 500, or 1,000 mg/kg for three consecutive days. No increases in the frequency of micronuclei were found for any dose group (ManTech Environmental Technology, 1998). There is some uncertainty whether the maximum tolerated dose was reached in the study. Typically, the assay is performed at 85 percent of the maximum tolerated dose, and the 1,000 mg/kg-day dose represents approximately 50 percent of the LD_{50}. Furthermore, there was no indication of toxicity to the bone marrow cells because the polychromatic erythrocyte/normochromatic erythrocyte ratio was not different from the controls. The test was later repeated by the National Institute of Environmental Health Sciences. Male $B6C3F_1$ mice were injected intraperitoneally with 0, 125, 250, 500, 1,000, 1,500, and 2,000 mg/kg ammonium perchlorate in buffered saline. Five mice per group were treated daily for three consecutive days, and were sacrificed 24 hours after the last injection. All animals in the 1,500 and 2,000 mg/kg groups died after the first injection and 4/5 animals in the 1,000 mg/kg group died after the second injection. All animals in the 125, 250, and 500 mg/kg groups survived the treatment. No increases in micronuclei were seen at any of the test doses, and the trend test was not positive (Zeiger, 1999). The negative results of the repeat study support the results of the first study.

The 90-day subchronic bioassay using Sprague-Dawley rats also evaluated micronuclei induction (Siglin *et al.*, 2000). Ten rats per sex were treated with ammonium perchlorate in drinking water for 90 days at 10 mg/kg-day. The results indicate that ammonium perchlorate under the test condition was not mutagenic to the bone marrow cells of male and female Sprague-Dawley rats. The chemical was not toxic to the bone marrow cells at the dose tested, as it did

not reduce the ratio of polychromatic to normochromatic erythrocytes in male or female rats.

Based on the above *in vitro* and *in vivo* genotoxicity test results, ammonium perchlorate does not appear to be mutagenic or clastogenic. Therefore, genotoxicity is not considered a potential mode of carcinogenic action for perchlorate.

Immunotoxicity

Shigan (1963) administered ammonium perchlorate to rabbits and white rats in water at 190 mg/kg-day for three months. The mode of administration was not described. No effect was found on immune function as evaluated by leukocyte phagocytosis (Shigan, 1963).

A series of hematological and immunotoxicology experiments in female $B6C3F_1$ or CBA/J Hsd mice were conducted as part of the U.S. EPA's perchlorate testing strategy (U.S. EPA, 2002). In these experiments, mice were exposed for 14 or 90 days to ammonium perchlorate at doses between 0.02 and 50 mg/kg-day via drinking water. The mice were tested at intervals for immunotoxicological effects such as delayed type hypersensitivity and cytotoxic lymphocyte activity (Keil *et al.*, 1998, 1999; Burleson Research Technologies, 2000).

In the hematological studies, no differences were observed between control and dosed mice in 14- or 90-day experiments for erythrocyte cell count, hemoglobin, hematocrit, mean corpuscular volume, and mean corpuscular hemoglobin concentration, nor in leukocyte differential counts of neutrophils, monocytes, and lymphocytes. An increase in the percentage of reticulocytes was observed in the peripheral blood of mice exposed to 3 mg/kg-day of ammonium perchlorate in a 90-day study. No consistent alteration in the bone marrow stem cell assay was observed. An increase in the number of colony-forming units was observed in bone marrow cell cultures from mice dosed at 30 mg/kg-day in a 14-day study. However, in two other 90-day studies, this positive result was not confirmed. Upon reviewing the immunotoxicological studies, U.S. EPA (2002) found that three immune function parameters were altered by ammonium perchlorate exposure: (a) suppression of *in vitro* peritoneal macrophage phagocytosis of *L. monocytogenes*; (b) enhancement of the plaque-forming cell (PFC) assay response to sheep red blood cells (SRBCs); and (c) enhancement of the local lymph node assay (LLNA) response to 2,4-dinitrochlorobenzene (DNCB).

Decreased *in vitro* phagocytosis of *L. monocytogenes* by peritoneal macrophages obtained from mice dosed for 14 days at 1 or 30 mg/kg-day (ammonium perchlorate) was observed. In mice exposed for 90-days, phagocytosis was decreased in all dose groups (Keil *et al.*, 1998, 1999). However, similar effects were not observed in a 90-day perchlorate exposure followed by a 30-day recovery period study. These *in vitro* data suggest that perchlorate suppresses the phagocytic capacity of peritoneal macrophages, but

this suppression is reversed after a 30-day recovery period. It is difficult to interpret the biological significance of this data set because *in vivo* study results indicate ammonium perchlorate exposure did not alter the ability of mice to combat *L. monocytogenes* infection. It was suggested that while perchlorate may reduce the phagocytic capacity of peritoneal macrophages, the ability of macrophages from other sites (e.g., spleen, liver) to clear *L. monocytogenes* was not altered (U.S. EPA, 2002).

The PFC assay is routinely used for identifying immunosuppressive chemicals. The reason why the highest dose(s) of ammonium perchlorate, given over 90 days, enhanced this response is not known. The enzyme-linked immunosorbant assay (ELISA) data for mice exposed to up to 30 mg/kg-day for 14 or 90 days do not corroborate this enhanced response to SRBCs observed in the PFC assay. The data from Burleson Research Technologies (2000) indicate that exposure to perchlorate enhances the LLNA response to DNCB. While a dose of 50 mg/kg-day for 14 days enhanced the response, the same dose for 90 days suppressed the response. Lower doses of 0.06 and 0.2 mg/kg-day also increased the response; however, interpretation of these data is made difficult by the observation that 2 mg/kg-day did not affect the response in the 14-day study. OEHHA agrees with U.S. EPA (2002) that interpretation of the results is made difficult by (a) some technical problems encountered in the studies, (b) the apparent inconsistency of the high-dose study results, and (c) the unknown biological significance of the response enhancement.

Neurotoxicity

By interfering with the thyroid-pituitary axis, perchlorate can interfere with development of the central nervous system. Thyroid hormone plays an essential role in the development of the corpus callosum and other brain structures. As part of the U.S. EPA's program to evaluate the toxicity of perchlorate, neurodevelopmental tests on Sprague-Dawley rats were conducted by Argus Research Laboratories (1998a; 2001). The study design and findings have been summarized in the "Developmental and Reproductive Toxicity" section.

6. DOSE-RESPONSE ASSESSMENT

Noncarcinogenic Effects

The primary effect of perchlorate exposure is the disruption of thyroid hormone regulation. This mode of action is supported by the results of a number of animal studies that show that perchlorate inhibits thyroidal iodide uptake, changes serum T3, T4, and TSH levels, causes thyroid enlargement, induces thyroid follicular cell hypertrophy and hyperplasia, and a number of other toxicological endpoints, as reviewed in the "Toxicological Effect in Animals" chapter. Similarly, the primary action of perchlorate in humans is inhibition of iodide uptake into the thyroid gland. The function of the thyroid gland is the production of thyroid hormone. Iodide is a key component in the structure of thyroid hormone, and by blocking its uptake into the thyroid, perchlorate can potentially cause decreased production of this hormone. Decreases in thyroid hormone have been associated with impaired neurodevelopment in children, increases in cardiovascular disease risk factors, and other adverse effects.

Selecting the Key Biochemical Effect

In developing PHGs, OEHHA is required by the California Safe Drinking Water Act of 1996 (Health and Safety Code Section 116365) to consider the existence of groups in the population that are more susceptible to adverse effects of drinking water contaminants than are typical healthy adults. The primary mechanism of perchlorate toxicity is inhibition of iodide uptake by the thyroid. Three groups that may be particularly susceptible to this effect of perchlorate due to alterations in iodine status are pregnant women, the developing fetus, infant or young child, or women with low iodine intake.

Thyroid stress of pregnancy: In his review paper, Glinoer (2001) suggested that pregnancy causes profound changes in thyroid function and represents a stress on the thyroid hormonal system. In the first trimester of gestation, there is an increased need for thyroid hormones and an increased need for iodine from the diet. When iodine nutrition levels are sufficient, physiological adaptation takes place. When iodine is restricted or deficient, adequate physiological adaptation is difficult to achieve and is progressively replaced by pathological alterations occurring in parallel with the degree of long-term iodine deprivation. Glinoer concluded, "Therefore, pregnancy typically reveals underlying iodine restriction and gestation results in an iodine-deficient status, even in conditions with only a marginally restricted iodine intake, such as is observed in many European regions."

Results of a prospective study reported by Kung *et al.* (2000) showed that in a borderline iodine-sufficient area (median urinary iodine level = 9.8 µg/dL), pregnancy can pose a stress on the thyroid, resulting in higher rates of maternal

goitrogenesis as well as neonatal hypothyroxinemia and hyperthyrotrophinemia. Thyroid enlargement in these women persisted and failed to revert completely even 3 months after delivery.

Susceptibility of the fetus, infant and young child: As reviewed above, several epidemiological studies provide evidence that iodine deficiency during pregnancy may adversely affect brain development and cause neurointellectual deficits in the offspring. These effects are not limited to areas with severe iodine deficiency and endemic cretinism; effects have been associated with levels of thyroid hormone that fall into what have traditionally been considered normal ranges. The severity of effects may depend on the timing and the severity of the iodine deficiency. In several studies conducted in areas with moderate or even mild iodine deficiency, mainly in southern Europe, it was shown that developmental abnormalities may occur in schoolchildren who are clinically euthyroid. Even borderline iodine deficiency might lead to impaired school performance in some children (Glinoer, 2001).

Since the thyroid is dependent on iodide for thyroid hormone production, inadequate iodine intake can lead to decreased thyroid hormone production. Studies in humans that have identified links between relatively small decreases in thyroid hormone levels during pregnancy and significant effects on cognition in the offspring include Pop *et al.* (1999, 2003), Haddow *et al.* (1999), Klein *et al.* (2001), Kooistra *et al.* (2006), and Vermiglio *et al.* (2004). These findings are supported biologically by animal studies that have linked decreases in maternal thyroxine (T4) during pregnancy to permanent structural changes in the brains of the offspring (Lavado-Autric *et al.*, 2003; Auso *et al.*, 2004; Gilbert and Sui, 2008). Importantly, some of these effects are seen at thyroid hormone levels that are within what has been traditionally defined as the normal range, and in pregnant mothers and offspring without any other evidence of clinical hypothyroidism.

One reason why the fetus, infant or the young child may be particularly susceptible to inadequate iodine intake and small changes in thyroid hormone levels is that the fetal and infant periods are critical times of brain and neurological development. Another reason may be that the fetus and infant do not have fully developed thyroids and have stores of thyroid hormone that are much lower than in adults (van den Hove *et al.,* 1999). These low stores may make them more susceptible to temporary decreases in iodine intake or other factors that may inhibit hormone production. Finally, some data suggest that many young children in the U.S. may not have an adequate iodine intake. Pearce *et al.* (2007) estimated that 47 percent of the breast milk samples in their study of 57 women from the Boston area did not contain enough iodine to meet the infant iodine intake recommended by the Institute of Medicine.

Women with low iodine intake in the U.S.: The rates of most thyroid diseases are much greater in women than in men. The reason for this is unknown, but it suggests that women might be more susceptible to environmentally-caused

thyroid problems than men. In Blount *et al.* (2006), statistically significant associations between increasing perchlorate and decreasing T4 and increasing TSH were seen in women but not in men. In addition, effects on T4 were only seen in women with evidence of somewhat reduced iodine intake (urinary iodine concentrations < 100 µg/L), but not in women with evidence of higher iodine intakes. These effects highlight the importance of gender and iodine status when assessing the potential impacts of perchlorate.

Urinary iodine concentration is an indicator of the adequacy of iodine intake for a population. According to the World Health Organization (WHO), the median urinary iodine concentrations in iodine-sufficient populations should be greater than 100 µg/L (WHO, 1994; as cited in Hollowell *et al.*, 1998). In the NHANES 2001-2, the geometric mean urinary iodine concentration in women was 126 µg/dL, which indicates an adequate iodine intake for the population as a whole. However, this level does not mean that every individual member of the population has an adequate iodine intake. In Blount *et al.* (2006), the perchlorate-T4 association was seen in women with spot urinary iodine levels below 100 µg/L, a group that included 37 percent of all women in the study. The fact that the women in this study were derived from an essentially nationally representative sample of all women in the U.S. suggests that a large number of U.S. women (e.g., 37 percent) have iodine intakes that may put them at risk for effects from perchlorate.

In summary, the primary mechanism of perchlorate toxicity is the inhibition of iodide uptake into the thyroid gland and a subsequent decrease in thyroid hormone production. Iodine deficiency and thyroid insufficiency have been linked to a number of significant adverse health effects including goiter, impaired cognitive development, and increases in cardiovascular risk factors. Some of these links have been seen at levels of iodine and thyroid hormones that have been considered to be within normal reference ranges. OEHHA has chosen to use reduced thyroidal iodide uptake as the key biochemical effect for the perchlorate PHG. This is the same key biochemical effect used in the OEHHA 2004 PHG perchlorate document and the same one used by the NRC in their report on the health implications of perchlorate exposure (OEHHA, 2004; NAS, 2005). The purpose of this PHG is to help prevent any inhibition of thyroidal iodide uptake that could potentially lead to the adverse effects described above.

Selecting the Critical Study

OEHHA used the 14-day perchlorate clinical dosing study of Greer *et al.* (2002) for its dose-response analysis in the 2004 perchlorate PHG document, and five percent inhibition of iodide uptake as the benchmark response (BMR). Greer *et al.* (2002) administered a daily oral dose of perchlorate to groups of male and female volunteers for 14 days at doses of 0.007, 0.02, 0.1, or 0.5 mg/kg-day. Reductions in iodide uptake by the thyroid gland were seen at all four dose levels, with statistically significant reductions at the highest three doses.

In this update, to determine a level of perchlorate exposure that would not inhibit thyroidal iodide uptake, OEHHA again has chosen the Greer *et al*. (2002) study as the critical study and applied the benchmark dose approach for identification of the point of departure. This was selected as the critical study because it was an experimental study in humans where subjects were given known doses of perchlorate and evidence of a dose-response relationship was seen with the key biochemical outcome, iodide uptake in the thyroid. Several other studies have linked perchlorate exposure to changes in thyroid hormones and these were evaluated as to whether they could be used for risk assessment. However, these were either based on ecologic measurements of perchlorate exposure or only a single or few urinary perchlorate measurements (e.g., Kelsh *et al.,* 2003; Blount *et al.,* 2006). Basing exposure on only a few measurements could bias true associations towards the null and lead to an underestimation of true risks. Nonetheless, we estimated a PHG using an analysis of the NHANES data, which is presented in the Appendix. Despite any possible exposure misclassification, this estimate comes quite close to that estimated using Greer *et al.* (2002) data.

Selecting the Point of Departure

The benchmark dose (BMD) is the dose associated with a predefined level of response, the benchmark response (BMR). For this analysis, a five percent decrease of mean radioactive iodide uptake by the thyroid is used as the BMR. A five percent decrease was selected because this is the lowest level of effect that is commonly detectable with statistical significance in many animal and human studies.

A statistical lower bound of the BMD, the 95 percent lower confidence limit (the BMDL), is used as the point of departure for defining an exposure level that is likely to be without an appreciable risk of deleterious effects in humans. Using the BMDL rather than the BMD helps to account for the uncertainty inherent in a given study and according to the U.S. EPA, "assures (with 95 percent confidence) that the desired response is not exceeded" (U.S. EPA, 2000).

U.S. EPA recommends BMD methods to estimate reference doses (RfDs), which are used along with other scientific information to set criteria and standards for noncancer human health effects. In the past, RfDs have mainly been determined from NOAELs, which represent the highest experimental dose for which no adverse health effects have been documented. As noted by U.S. EPA and many others, the BMD approach has several significant advantages over the NOAEL approach when appropriate dose-response data, like those in Greer *et al.* (2002), are available. Using the NOAEL to determine RfDs has long been recognized as having a number of limitations. One is that the NOAEL is limited to only one of the doses in the study and is highly dependent on study design; in particular, the dosages selected by the investigators. In most clinical studies, like Greer *et al.* (2002), only a relatively small number of dose levels are selected. Because the level selected as the NOAEL has to be one of the doses evaluated in the critical

study, the NOAEL is highly dependent on the dose levels chosen by the investigator.

Another weakness is that the NOAEL is highly dependent on the size of the study. The reason for this is that it is usually defined as the highest dose at which there is no *statistically significant* observable effect, and statistical significance is highly dependent on sample size. All else being equal, the larger the sample size, the more likely a finding of a given magnitude (e.g., a 5% decrease in iodide uptake) will be statistically significant. Thus, two studies (one large and one small) may both find the same 5% effect at a particular dose, but this 5% could be statistically significant in the larger study but not in the smaller study. In this example, the 5% effect could be real in both studies, but would be selected as the NOAEL in the smaller study for the sole reason that the investigators did not include more subjects. The same arguments apply to using a NOEL. In the Greer *et al*. (2002) study, a small decrease in iodide uptake by the thyroid was seen in those subjects receiving the lowest perchlorate dose. As seen in Figure 12, the magnitude of this effect is about what was expected based on the magnitudes of the effect sizes seen in the higher dose groups. In a larger study, this may have been statistically significant and considered a LOEL. However, the sample size was small (there were only seven subjects in the lowest dose group), and this small effect size was not statistically significant and thus considered a NOEL. It is possible that this effect was due to chance in Greer *et al*. (2002). However, it is also possible this effect is real or that the actual effect is even higher than observed but ended up being lower due to chance.

In the BMD approach, this is not an issue. This approach involves estimating effect sizes based on the entire dose-response curve, that is, all of the dose levels, all of the sample sizes at each dose level, and all of the effect sizes at each dose level. As such, it is not reliant on any single dose and therefore much less reliant on the doses chosen by the investigator, on the sample size at any single dose level, or the statistical significance of any single result. Sample size is still important in the BMD method in that the results of each dose are partially weighted by the number of subjects at each dose level and in calculating the BMDL.

A final advantage of the BMD approach is that because all dose levels are considered, the shape of the dose-response curve throughout the entire dose range, especially at the lower doses, is taken into account. This can potentially allow for a more accurate estimation of the true effects occurring in the lower dose ranges.

For all of these reasons, OEHHA has chosen to use the BMD approach rather than the NOEL approach. As discussed below, this had only a relatively small impact on the PHG.

Calculation of the BMD Using Greer *et al.* (2002)

OEHHA used the BenchMark Dose Software, version 2.0.0.33 (U.S. EPA, 2008a) to perform the analyses based on the human data reported by Greer *et al.* (2002) shown in Table 45. This is the same analysis, using the same data from Greer *et al.* (2002) that was used in the OEHHA 2004 perchlorate PHG document. A detailed discussion of the application of the software is provided in a U.S. EPA (2012) document, "Benchmark Dose Technical Guidance."

OEHHA tried several curve fitting models provided by the software and found the Hill model adequately describes the data (goodness of fit test, p=0.46), shown plotted in Figure 12. The fit is generally considered adequate when the p-value is greater than 0.10. Other models, including linear and polynomial models, fit the data poorly based on visual inspection and goodness of fit p-values.

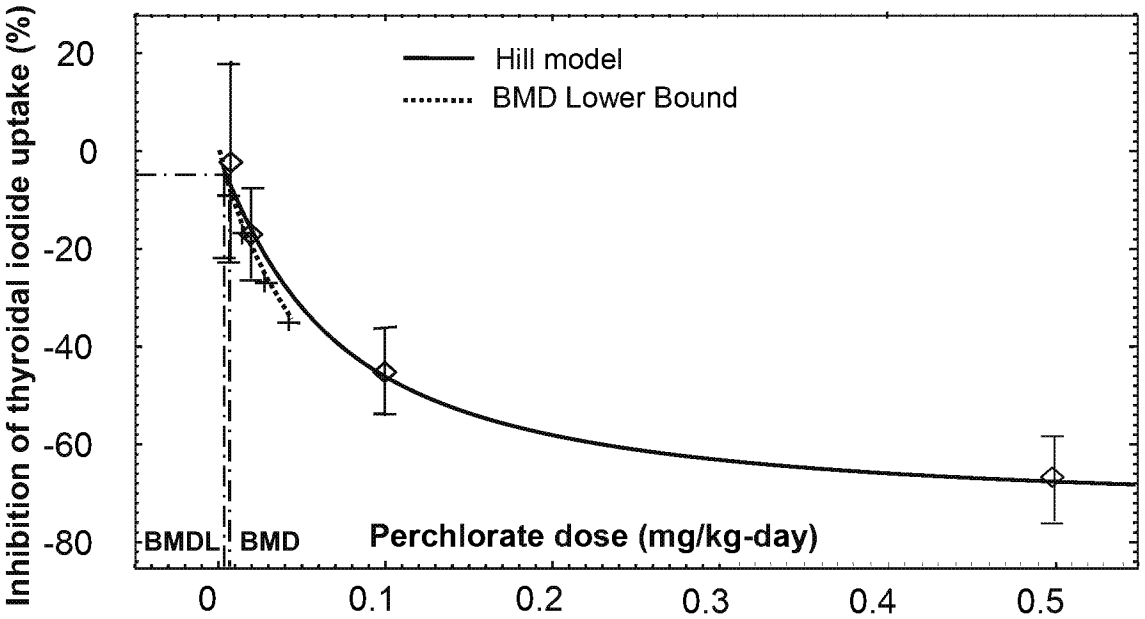

Figure 12. Analysis of the Greer *et al.* (2002) Data by the Benchmark Dose Approach. The Hill model was run with the following settings: intercept = zero, power parameter restricted to be greater than one, a constant variance model assumed. The BMR was a 5 percent decrease in iodide uptake.

The form of the response function estimated by the model is as follows:

$$\text{Response} = \text{intercept} + (v \times \text{dose}^n) / (k^n + \text{dose}^n)$$

where:

intercept = 0
v = -67.076

n = 1.43546
k = 0.0684664

The estimated BMD and BMDL corresponding to a five percent reduction of the mean thyroidal iodide uptake are 0.0068 mg/kg-day and 0.0037 mg/kg-day, respectively. These are the same BMD and BMDL calculated in the 2004 OEHHA perchlorate PHG document. It should be noted that the BMDL of 0.0037 mg/kg-day is lower than the lowest dose tested, 0.007 mg/kg-day, in the Greer *et al*. (2002) study.

Table 45. Human Data from Greer *et al*. (2002)

Average dose (mg/kg-day)	Change in 24 hr radioactive iodine uptake by the thyroid (%)		Number of subjects in each dose group
	Average	Standard deviation	
0.007	-1.844	22.019	7
0.02	-16.393	12.828	10
0.1	-44.693	12.32	10
0.5	-67.076	12.114	10

For comparison, significant changes in serum T3, T4, and TSH levels were observed even at the 0.01 to 0.1 mg/kg-day dose range for perchlorate in adult rodents. Rat fetuses and rat pups are reportedly more sensitive to the effects of perchlorate than adult rats. In several reproductive and developmental studies, colloid depletion of the thyroid, thyroid hypertrophy, and abnormal brain development were found in rat pups exposed to perchlorate *in utero* and after birth. Based on these study results (Springborn Laboratories, 1998; Argus Research Laboratories, 2001), a LOAEL of 0.01 mg/kg-day can be identified.

Carcinogenic Effects

There are two published epidemiological studies that investigated the association between perchlorate in drinking water and cancer (Li *et al*., 2001; Morgan and Cassady, 2002). Based on the reported data, it does not appear that perchlorate was associated with increased risks of cancer in the two study areas during the study periods, under the limitations of the studies.

Several subchronic oral studies in rodents showed that perchlorate induced hypertrophy and hyperplasia in the thyroid gland (Caldwell *et al*., 1995; Springborn Laboratories, 1998; Argus Research Laboratories, 1998b, 1998d, 1999, 2001; Keil *et al*., 1998). In two chronic oral studies, perchlorate at relatively high concentrations (over 1,000 mg/kg-day) was shown to produce thyroid follicular cell tumors in rats (Kessler and Kruskemper, 1966) and mice (Pajer and Kalisnik, 1991). However, only benign tumors were observed in the

study reported by Kessler and Kruskemper (1966), and inadequate reporting and low survival of the control and exposed animals lowered confidence in the results reported by Pajer and Kalisnik (1991). Each study had only one perchlorate exposure group. In a developmental study reported by Argus Research Laboratories (1999), thyroid follicular cell adenomas were also observed in two male Sprague-Dawley rats (2/30) exposed to 30 mg/kg-day perchlorate *in utero* and after birth. No such tumors were found in the vehicle control (0/30). Though the incidence is not significant using standard tests (e.g., Fisher's exact test), the fact that the tumors were found in 19-week old rats and the historical incidence of this type of tumor in male Sprague-Dawley rats in 2-year studies reported in the literature is only 3-4 percent makes the finding noteworthy (U.S. EPA, 2002).

Complex anions structurally similar to perchlorate, such as pertechnetate (TcO_4^-), perrhenate (ReO_4^-) and tetrafluoroborate (BF_4^-), are also capable of inducing thyroid follicular cell neoplasia in test animals (Green, 1978, as cited in Paynter *et al.*, 1988). Based on the limited data available, there are reasons to believe that perchlorate is a potential carcinogen in rodents.

After reviewing thyroid carcinogenesis in rodents and in humans, U.S. EPA (1998b) in the "Assessment of Thyroid Follicular Cell Tumors" stated that "in spite of the potential qualitative similarities, there is evidence that humans may not be as sensitive quantitatively to thyroid cancer development from thyroid-pituitary disruption as rodents. Rodents readily respond to reduced iodide intake with the development of cancer, humans develop profound hyperplasia with "adenomatous" changes with only suggestive evidence of malignancy. Even with congenital goiters due to inherited blocks in thyroid hormone production, only a few malignancies have been found in humans."

One factor that may play a role in interspecies quantitative sensitivity to thyroid stimulation is the influence of protein carriers of thyroid hormones in the blood. In humans, other primates, and dogs a high affinity thyroxine-binding globulin tightly binds T4 (and T3 to a lesser degree); this protein is missing in rodents, rabbits and lower vertebrates. As a result, T4 bound to proteins with lower affinity in the rodent is more susceptible to removal from the blood, metabolism, and excretion from the body. As shown in Table 46, the estimated serum half-life of T4 is much shorter in rats (<1 day) than in humans (5-9 days). This shorter T4 half-life in rats requires a higher level of serum TSH and T4 production rate than in the adult human (U.S. EPA, 1998b). Thus, it appears that the rodent thyroid gland is chronically stimulated by TSH levels above basal levels to compensate for the increased turnover of thyroid hormones, and this in turn could move the gland towards increased growth and potential neoplastic change more readily than in humans. It is interesting to note that adult male rats have higher serum TSH levels than females, and they are often more sensitive to goitrogenic stimulation and thyroid carcinogenesis. In humans, there is no sex difference in hormone levels, but females much more frequently develop thyroid cancer (U.S. EPA, 1998b).

Some of the studies summarized in this document provide some evidence of a quantitative difference in the thyroid responses of humans and rodents to perchlorate, based on applied dose. Several 14-day drinking water studies showed significant depression in serum T3, T4, and elevation in serum TSH levels in rodents exposed to doses as low as 0.01 or 0.1 mg/kg-day (Caldwell *et al.*, 1995; Springborn Laboratories, 1998; Keil *et al.*, 1998; Yu *et al.*, 2000). By contrast, serum T3, T4, and TSH levels in healthy adult humans that are not iodine deficient are much less sensitive to perchlorate exposure. For instance, after exposure to perchlorate in drinking water as high as 12 mg/kg-day for 1, 2, or 4 weeks, no significant changes in serum T3 and T4 levels were found in male volunteers. Serum free T4 and TSH levels were significantly depressed following perchlorate exposure when compared to those before exposure (Brabant *et al.*, 1992; Mattie, 2000). A significant reduction in intrathyroidal iodine concentration was also noticed in the study reported by Brabant *et al.* (1992). Lawrence *et al.* (2000) found no change in serum T3, T4, and TSH in male volunteers exposed to perchlorate in drinking water at 0.14 mg/kg-day for 1 and 2 weeks. Greer *et al.* (2002) exposed male and female volunteers to perchlorate in drinking water at 0.02, 0.1, or 0.5 mg/kg-day for 2 weeks and collected blood samples on days 1, 2, 3, 4, 8, and 14. Statistically significant depression of iodide uptake by the thyroid was observed in the upper two dose groups. However, no significant depression in serum T3 and T4 nor elevation in serum TSH was observed. No dose-response relationships were noticed for these thyroid and pituitary hormones. These data show that though a similar mode of action of perchlorate is operative in rodents and humans, the sensitivities of serum T3, T4, and TSH levels of the two species to perchlorate may not be the same. However, this remains to be fully elucidated. Greer *et al.* (2002) and the other clinical studies cited above only evaluated healthy adults, not sensitive members of the human population such as pregnant women and their fetuses, women with low iodine status, people with thyroid disease, or infants. There is some epidemiological evidence that lower levels of chronic perchlorate exposure seen in the NHANES data (Steinmaus *et al.,* 2010) affect newborn thyroid function.

Table 46. Inter- and Intraspecies Differences of T3, T4, and TSH Levels and Sensitivity to Thyroid Cancer (Modified from U.S. EPA, 1998b)

Parameter	Human	Rat
Thyroxine-binding globulin	Present	Essentially absent
T4 half-life	5-9 days	0.5-1 day
T3 half-life	1 day	0.25 day
$\frac{\text{T4 production rate}}{\text{kg body weight}}$	1 ×	10 × that in humans
TSH	1 ×	6-60 × that in humans
Follicular cell morphology	Low cuboidal	Cuboidal
Sex differences		
Serum TSH	Sexes equal	Male $\leq$ 2 × Female
Sensitivity to thyroid cancer	Female = 2.5 × Male	Male > Female

In evaluating a thyroid carcinogen, it is important to determine the mode of action as it impacts the choice of models in high-to-low dose extrapolation. In the "Assessment of Thyroid Follicular Cell Tumors," U.S. EPA (1998b) stated that in order to show the antithyroid activity of a chemical is the cause of thyroid tumors observed in rodents, it is necessary to demonstrate the following:

1. Increases in thyroid growth;
2. Changes in thyroid and pituitary hormones (considered to be the most important);
3. Location of the sites of antithyroid action (documents where in the body the chemical under assessment leads to perturbations in thyroid-pituitary function);
4. Dose correlations among various effects (to determine where the growth curve for the thyroid gland deviates from the normal pattern of cell replacement and how this relates to doses producing tumors); and
5. Reversibility of effects following treatment cessation during the early stages of disruption of the thyroid-pituitary axis (shows that permanent, self-perpetuating processes have not been set into motion).

The available toxicity data of perchlorate appear to have fulfilled the five requirements described above. Several *in vitro* and *in vivo* genotoxicity studies have been performed on perchlorate. Under the testing conditions, none of the tests indicates perchlorate is a genotoxic agent. Perchlorate is known to inhibit the uptake of iodide in the thyroid, thereby causing a reduction in the hormones T3 and T4. Subchronic and chronic drinking water studies showed that perchlorate exposure depressed serum T3 and T4 but elevated serum TSH

levels in rodents and rabbits. At higher exposure levels, thyroid follicular cell hypertrophy, thyroid follicular cell hyperplasia, and increased thyroid weights were also observed in adults as well as postnatal rats, as described in the chapter "Toxicological Effects in Animals."

There is also evidence that the thyroid follicular cell hypertrophy and hyperplasia observed in rats exposed to ammonium perchlorate might be reversible. In the study reported by the Springborn Laboratories (1998), absolute and relative thyroid/parathyroid weights were significantly increased in male rats exposed to 10 mg/kg-day for 14 days as well as 90 days. However, no significant increases in both absolute and relative thyroid/parathyroid weights were observed in male rats exposed to 10 mg/kg-day for 90 days, followed by a 30-day recovery period. Similarly, absolute and relative thyroid/parathyroid weights were significantly increased in female rats exposed to 10 mg/kg-day for 90 days, but no significant increases in terms of both absolute and relative thyroid/parathyroid weights were observed in female rats exposed to 10 mg/kg-day for 90 days, followed by a 30-day recovery period.

The available data suggest that thyroid tumors observed in rodents exposed to perchlorate via the oral route are likely to be caused by the disruption of thyroid-pituitary homeostasis. It follows that if there were no thyroid and pituitary hormone changes, and no thyroid follicular cell hypertrophy and hyperplasia, there would be no thyroid tumors. For this reason, the perchlorate dose determined for prevention of a detectable decrease in T4 in humans (noncarcinogenic effect) is reasoned to be protective against thyroid tumors as well.

There are no adequate data from human studies to evaluate the cancer potency of perchlorate. Several studies in laboratory animals have reported increases in thyroid tumors following perchlorate exposures, although these have involved doses that are orders of magnitude higher than the exposure levels seen in the dose-response data OEHHA used for BMD modeling. Furthermore, there are difficulties in estimating the cancer potency of perchlorate based on animal cancer data because of differences in iodine deficiency and thyroid disease status (background rates) in laboratory animals compared to humans. For these reasons, a quantitative dose-response evaluation was not performed for the possible carcinogenic effects of perchlorate. It is reasoned that by setting the perchlorate PHG low enough to avoid impacts on thyroid hormone status, all other potential adverse thyroid effects, including benign and malignant thyroid tumors, will be prevented.

7. CALCULATION OF THE PHG

The PHG is derived in this section by first calculating an Acceptable Daily Dose, or maximum amount that can be consumed without toxic effects, using the BMD value derived from the human study by Greer *et al.* (2002) in the last chapter. This is then converted into an acceptable drinking water perchlorate concentration. In making these calculations, population subgroups that may be much more susceptible to the effects of perchlorate than healthy adults and perchlorate exposures from sources besides drinking water are taken into account. The resulting updated PHG will help prevent perchlorate-related reductions in thyroidal iodide uptake and subsequent decreases in thyroid hormone production that may be associated with adverse health effects.

A quantitative dose-response evaluation was not performed for the possible carcinogenic effects of perchlorate. By setting the perchlorate PHG low enough to avoid impacts on thyroid hormone status, all other potential adverse thyroid effects, including benign and malignant thyroid tumors, are assumed to be prevented.

Acceptable Daily Dose (ADD)

For estimation of a health-protective concentration of perchlorate in drinking water, an acceptable daily dose (ADD) of the chemical from all sources will first be calculated. This involves incorporation of appropriate estimates of uncertainty in the extrapolation of the dose leading to the key biochemical effect from human or animal studies to the estimation of a lifetime ADD that is unlikely to result in or lead to any toxic effects. For this purpose, the following equation can be used:

$$\text{ADD} = \frac{\text{NOAEL/LOAEL/BMDL in mg/kg-day}}{\text{UF}}$$

where,

ADD = estimated maximum daily dose that can be consumed by humans for an entire lifetime without toxic effects;

NOAEL/LOAEL/BMDL= no-observed-adverse-effect level, lowest-observed-adverse-effect level, or lower limit on the benchmark dose estimated from the critical study;

UF = uncertainty factor(s).

For this case, OEHHA chose to estimate the ADD from the lower limit of the two-sided 95 percent confidence interval of the perchlorate dose estimated to cause a five percent reduction in iodide uptake in the thyroid gland based on the findings of Greer *et al.* (2002).

An uncertainty factor of 10 is applied to help account for interindividual variability in the population that was not captured by the Greer *et al.* (2002) study. This factor is used to account for uncertainty in interindividual differences in toxicodynamic and toxicokinetic factors that may impact susceptibility. It is not intended to account for drinking water intake rates and actual estimates of perchlorate intake and exposure, which are incorporated separately. The Greer *et al.* (2002) study included only 37 healthy adults so the variability of the study data is likely to be smaller than that in the general population. Furthermore, the study population did not specifically examine individuals with low iodine intake, pregnant women, infants, or with the other potential susceptibility factors. Potentially susceptible groups include:

- Neonates and infants, who may be susceptible to perchlorate for several reasons:

    a. Infancy is a critical period for development of the brain and nervous system, processes that are critically reliant on adequate supplies of thyroid hormone. The role that thyroid hormone plays in these critical developmental processes highlights the potential importance of any agent, like perchlorate, whose mechanism involves alterations in thyroid hormone production.

    b. Some data suggest that neonates have stores of thyroid hormone and iodide that are much less than those in adults (Van den Hove *et al.*, 1999). This would make neonates less able than adults to respond to any factor that temporarily decreases iodine intake, iodide uptake, or thyroid hormone production.

    c. Data from several studies (Kelsh *et al.,* 2003; Brechner *et al,.* 2000; Steinmaus *et al.,* 2010; and others) provide evidence of a possible link between perchlorate in drinking water during pregnancy and thyroid hormone levels in newborns.

    d. Preterm infants may be the subgroup most at risk for impairment in thyroid hormone production caused by a reduction in iodine intake or iodide uptake by the thyroid. Intrathyroidal stores of thyroid hormone and iodide are markedly less in preterm infants than in full term infants (van den Hove 1999). In addition, preterm infants have immature pituitary-thyroid function, and lose the contribution of maternal thyroid hormone at birth. Preterm infants also can have immature gastrointestinal function which could reduce their iodine intake.

    e. Since the primary mechanism of perchlorate toxicity is reduced iodide uptake by the thyroid, individuals who are already iodine deficient may be particularly susceptible to perchlorate toxicity. Importantly, the breast milk of many women may not provide an adequate iodine intake for the breast-fed child.

- Women with low iodine intakes. In Blount *et al.* (2006), statistically significant associations between increasing perchlorate and decreasing T4 were seen in women with urinary iodine levels below 100 µg/L, but not in women with higher iodine levels. Estimates from NHANES 2001-2 suggest that 37 percent of all women in the U.S. have urinary iodine levels below 100 µg/L (Blount *et al.*, 2006).

- The developing fetus. Studies have shown that decreases in maternal T4 during pregnancy, even relatively small ones, can lead to significant cognitive deficits in the offspring.

- Lactating women. Lactating mothers are considered a potentially sensitive subpopulation for effects of perchlorate because their need for iodine is greater than other adults. They are therefore at greater risk of getting an insufficient amount of iodine from the diet. The NAS (2001) suggests an Estimated Average Requirement and a Recommended Dietary Allowance of iodine almost two-fold higher for lactating mothers than for other adults.

- Pregnant women, who also have increased iodine requirements.

- People with thyroid diseases.

- People with high levels of thiocyanate, which typically comes from food or tobacco smoking. Data from Steinmaus *et al.* (2007) suggest that the magnitude by which perchlorate reduces T4 levels is about two times greater in people with high thiocyanate levels than in people with average or low thiocyanate levels (Table 40).

In summary, an uncertainty factor of 10 is applied to account for all sensitive groups, including infants, who may be more susceptible to perchlorate than the 37 healthy research volunteers in Greer *et al.* (2002). OEHHA notes that the uncertainty factor of 10 that used here is the same as the uncertainty factor of 10 recommended and used by the NRC to calculate its most recent perchlorate reference dose for U.S. EPA (NAS, 2005).

OEHHA considered an additional uncertainty factor of three to account for the short duration of the Greer *et al.* (2002) study. However, there is evidence in this study that iodide uptake is inhibited fairly quickly after exposure begins and the inhibition does not increase or increases only slightly as exposure continues. That is, in the three highest dose groups (those in which statistically significant reductions in iodide uptake were seen), the greatest proportion of the inhibition occurred by the second day of dosing and either did not worsen or worsened only slightly by day 14 of dosing. Furthermore, it can be argued that if there is no reduction in thyroidal iodide uptake, there will be no concomitant reduction in stored iodide, and extending the exposure duration is not likely to have an impact on the thyroid function. For this reason, OEHHA decided against an additional factor to account for the short duration of the critical study.

Given an uncertainty factor of 10 to account for increased susceptibility in infants,

$$\text{ADD} = \frac{3.7\ \mu g/kg\text{-}day}{10} = 0.37\ \mu g/kg\text{-}day$$

Public Health Protective Concentration (C)

Calculation of the updated public health protective concentration (C) for perchlorate in drinking water uses the following equation for noncarcinogenic endpoints:

C = ADD µg/kg-day × (BW/WC) × RSC

where:

(BW/WC) = the ratio of body weight (kg) and tap water consumption rate (L/day); the ratio for the 95th percentile of infants age 0-6 months is estimated to be 4.2 kg-day/L (OEHHA, 2012; Table 47); and

RSC = relative source contribution. A value of 0.73 (73 percent from water) is used to account for exposure of infants to perchlorate in their diet.

The 95th percentile water consumption rate and body weight ratios are based on water intake estimates derived by OEHHA (2012). These rates were based on data from the Continuing Survey of Food Intake of Individuals (CSFII) for the years 1994-1996, 1998. The CSFII was a large multistage probability sample collected by the U.S. Department of Agriculture involving over 20,000 individuals from throughout the U.S. The CSFII survey collected data on food and beverage intakes for two 24-hour non-consecutive periods, 3-10 days apart. These data were based on recall of dietary and water intake information, and it is possible that intake is overestimated in some people, and underestimated in others. These errors could balance each other out. Overall, their true impact is unknown although there is no reason to believe they were large. Because these data are based on the average of two separate assessments of drinking water intake in each individual collected 3-10 days apart, they are more likely to represent true longer-term intake patterns than data collected using a single day survey.

Using the CSFII data, the U.S. EPA Office of Water estimated the amount of water consumed by each individual (U.S. EPA 2004). For all demographic groups except infants, this included both water consumed directly from the tap for drinking (direct water) and water from the tap used to prepare beverages and foods, either at home or at a food service establishment (indirect water). OEHHA used these U.S. EPA estimates for those subjects reported to be drinking water consumers only since these are the people most likely to have the greatest exposures from local public drinking water sources (OEHHA, 2012).

For infants, OEHHA also used data from the CSFII but derived water intake rates based on the water used by infants consuming reconstituted formula. In order to identify infants who received reconstituted formula, OEHHA reviewed the food descriptions provided for the formula consumed by each infant in the CSFII. The amount of reconstituted formula consumed was then multiplied by the percent of indirect water in each type of reconstituted formula in order to calculate the amount of water consumed by each infant. Sample weights provided in the CSFII dataset were used to weight each individual's intake according to the number of infants in the population that he/she represented and these data were used to calculate distributional characteristics including 95th percentiles. The 95th percentiles rather than the means or medians were used to calculate the health protective concentration since this accounts for the fact that some people have much higher drinking water intake rates (and thus much higher intake of chemicals in their drinking water) than others. Further details and justification of these estimates are provided by OEHHA (2012).

Water intake rates for the various population groups used to calculate health-protective concentrations are shown in Table 47. OEHHA is focusing on infants in these calculations based on the variety of data discussed above showing that this group may be particularly susceptible to perchlorate. This includes the studies from California and elsewhere that provided evidence that thyroid hormone levels in infants were adversely affected by relatively low perchlorate exposure levels (Kelsh *et al.,* 2003; Brechner *et al*., 2000; Buffler *et al.,* 2006; Steinmaus *et al*., 2010; Li *et al.,* 2000a; Crump *et al.,* 2000). It also includes the data discussed above suggesting that many infants may not be receiving adequate iodine in their diets and that young infants have low stores of thyroid hormone (less than one day's worth compared to several weeks' worth in adults) (van den Hove *et al*., 1999; Pearce *et al.,* 2007). In addition, formula-fed infants have much higher water intake rates than older children and adults. Thus, their exposure to perchlorate from drinking water on a body weight basis at a given perchlorate concentration in drinking water will be considerably higher than in children or adults.

Food and water are the primary sources of exposure to perchlorate for most people. Perchlorate has been detected in a wide variety of foods, including fruits, vegetables, grains, dairy milk, and human breast milk (Kirk *et al*., 2005; Pearce *et al*., 2007; Murray *et al*., 2008). Perchlorate levels in urine from NHANES 2001-2, as reflected in the analysis of Blount *et al*. (2006), are generally supportive of the analysis of estimated intakes of perchlorate from foods provided by the U.S. FDA (U.S. FDA, 2009). Together, these data demonstrate that food is the primary source of perchlorate for the general population.

Estimates of perchlorate intake from food were derived from the U.S. FDA's Total Dietary Survey 2005–2006 as reported in U.S. EPA, 2008b. The RSC was defined as the proportion of the ADD not derived from food, and was calculated using the following equation:

RSC = (ADD – estimated perchlorate intake derived from food) / ADD

For most adults, including pregnant and lactating women, the mean perchlorate intake from food was estimated to be 0.10 µg/kg-day. At an ADD of 0.37 µg/kg-day, the RSC then equals 0.73, or 73 percent of the acceptable dose available for consumption in tap water.

The U.S. FDA Total Diet Survey did not provide information on perchlorate intake in infants less than 6 months old. In addition, this survey did not report estimates of perchlorate intake in analyses that only included infants who are formula-fed. Since the intake of perchlorate from food in formula-fed infants could be substantially higher than that in breast-fed infants, failure to specifically evaluate this group could have resulted in a PHG that was not adequately protective in formula-fed infants. Schier *et al.* (2010) measured perchlorate concentrations in 15 different powdered infant formulas (using perchlorate free water) and calculated mean perchlorate intake values based on the estimated daily ingested volume of formula. Perchlorate concentrations in formula varied by formula type and ranged from 0.03-5.05 µg/L, and the estimated geometric mean intake of perchlorate from the different formula types ranged from 0.03 to 0.29 µg/kg-day, with an average of 0.10 µg/kg-day. Using this average and the equation above, an RSC of 0.73 is also estimated for infants.

Using this RSC, the health-protective concentration (C) for infants is estimated to be:

C = 0.37 µg/kg-day x 4.2 kg-day/L x 0.73
C = 1.13 µg/L = 1 µg/L (ppb) (rounded)

Table 47 shows the values of C calculated for infants compared to those for other subpopulations. A relative source contribution of 73 percent and an uncertainty factor of 10 were used in all calculations.

Table 47. Estimated Health Protective Water Concentrations (C) of Perchlorate for Various Subpopulations, Assuming Intakes of Perchlorate in Food of 0.10 µg/kg-day[a] and an RSC of 0.73[b]

Group	Drinking Water Intake (L/kg-day)[c]	BW/WC (kg-day/L)	C (µg/L)
Infants (< 6 months old)	0.237	4.2	1.13
Pregnant women	0.043	23.3	6.29
Lactating women	0.055	18.2	4.92
Females (age 15-44)	0.038	26.3	7.10
Adults (16+)	0.045	22.2	6.00

[a]Based on estimated adult intakes using data from the 2005-6 U.S. FDA Total Dietary Study (U.S. EPA, 2008b) and infant intake from the data of Schier *et al.* (2010).
[b]Calculated as: (ADD – estimated food perchlorate intake) / ADD).
[c]95th percentile intake for drinking water consumers including both direct and indirect water for groups other than infants. For infants, drinking water intake is based on water used to reconstitute infant formula (OEHHA. 2012).

Based on these estimates, OEHHA calculated a PHG of 1 ppb (µg/L). OEHHA concludes that this level is health protective for lifetime exposure to perchlorate in drinking water, and is protective of sensitive populations including infants, pregnant women and their fetuses, those with low intake of iodine or high intake of other thyroid iodide uptake inhibitors, and other potentially susceptible groups.

A benchmark dose analysis was also done using the NHANES 2001-2 data discussed above (Blount *et al.,* 2006), and this provided results similar to those obtained using the Greer *et al.* (2002) data (see Appendix). The NHANES 2001-2 analysis required several data transformations, which greatly increased its complexity. The analysis using the Greer *et al.* (2002) data was used to calculate the final updated PHG since it is an experimental study where exposure levels are known for more than just a single point in time.

8. RISK CHARACTERIZATION AND CONCLUSION

Exposures to Perchlorate

In NHANES 2001-2, an essentially nationally representative sample of people ages ≥12 years in the U.S., perchlorate was detected in the urine of every one of the 2,820 people tested (Blount *et al.*, 2007). This suggests that probably everyone in California, as well as everyone in the U.S., is exposed to perchlorate through some source.

The primary routes of exposure are through food and water. In a recent study by the U.S. FDA, perchlorate was found in many commonly consumed foods including dairy products, fruits, and vegetables (U.S. FDA, 2009). In fact, perchlorate was detected in at least one sample of over 70 percent of the individual food items tested. The U.S. EPA recently estimated that as many as 16.6 million people in the U.S. may be drinking water with perchlorate concentrations greater than 4 ppb (U.S. EPA, 2008a). In California, from 2010 to 2013, detectable levels of perchlorate were reported in 248 public drinking water sources (Table 2) (SWRCB, 2014). The Colorado River is also known to be contaminated with perchlorate, and this water source is used by several large public drinking water agencies in California. For both the U.S. EPA and the California SWRCB surveys discussed above, analyses were based on detection limits of 4 ppb, and it is possible that millions more people are exposed at levels below this. This highlights the potential widespread perchlorate exposure in California that may be occurring from public drinking water sources.

Currently, the actual number of people that are likely to be affected by perchlorate from public drinking water in California is unknown. However, given the data above suggesting that hundreds of public water sources in California contain perchlorate, and given that potential susceptible groups including infants and women with low iodine intake represent a large fraction of the entire population, the number of people that may be affected by perchlorate exposure through their public water supplies is likely to be quite large.

Perchlorate in water can be naturally occurring as well as a result of industrial contamination. The fact that it can occur naturally does not decrease the potential health consequences of exposure. Many naturally occurring chemicals such as arsenic, lead, and asbestos are also toxic and measures are taken to reduce human exposures. Thus, the PHG is based on perchlorate exposure in drinking water whether its presence is due to natural or man-made events.

Health Impacts of Perchlorate

There is a continuum in the possible health effects from perchlorate exposure resulting from its effects on the thyroid, and some susceptible groups or individuals may have perchlorate-related effects at exposures that are lower than those causing similar effects in healthy individuals. For fetuses, infants and children, there is the potential for abnormal growth and development. Of particular concern are effects on brain development. Decreases in thyroid hormone production in infants are related to decreases in IQ. Much of the knowledge on the potential effects of perchlorate comes from extensive data on iodine deficiency in humans.

OEHHA considers effects on thyroid hormone production and subsequent changes to be adverse. Iodide uptake inhibition is the key event that leads to other possible effects from perchlorate exposure. Prevention of iodide uptake inhibition prevents progression to the adverse health effects of perchlorate. The inhibition of iodide uptake by perchlorate has been clearly documented in humans. The National Academy of Sciences (NAS, 2005) deemed "inhibition of iodide uptake by the thyroid as the basis of the perchlorate risk assessment to be the most health-protective and scientifically valid approach." OEHHA agrees with this approach and used it in developing its original 2004 PHG for perchlorate.

The Greer *et al.* (2002) study was used to characterize perchlorate's inhibition of iodide uptake for both the current PHG and the 2004 PHG. It might be argued that the magnitudes of the effects seen in the Greer *et al.* (2002) study were relatively small, and might not be noticeable in otherwise healthy individuals. However, this ignores the impact of these effects on a population basis. Any downward shift in the mean level of the thyroid hormone T4 in a population could increase the number of people who fall into the range of T4 values that are associated with high risks of either subtle or overt thyroid-related disease and toxicity (Miller *et al.,* 2009).

The purpose of the perchlorate PHG is to identify a level of perchlorate in drinking water that prevents any perchlorate-related reduction in thyroid iodide uptake that might lead to decreases in thyroid hormone production. Evidence suggests that even small decreases in thyroid hormone levels may be associated with significant adverse effects, including altered cognitive development in children and increased cardiovascular risk factors in adults. Importantly, these changes have been seen at thyroid hormone levels that are within what have been traditionally defined as normal reference ranges, and have occurred in people without any other evidence of overt thyroid disease. These findings suggest that small changes in thyroid hormone levels may be associated with at least some increased risk of thyroid-related adverse outcomes.

Health Value for Perchlorate from the Greer et al. (2002) Study

OEHHA used the BMD approach rather than the no-observed-effect level (NOEL) approach for the following reasons. OEHHA, like U.S. EPA, has chosen to use the BMD approach as the standard method in dose calculations, provided there are sufficient data to do so. As the U.S. EPA (2012, p. viii) notes, the BMD approach "involves dose-response modeling to obtain BMDs, i.e., dose levels corresponding to specific response levels near the low end of the observable range of the data, incorporates and conveys more information than the [NOAEL; no-observed-adverse-effect level] or [LOAEL; lowest-observed-adverse-effect level] process traditionally used for noncancer health effects." The NAS (2009, p. 129) in its review of U.S. EPA risk assessment practices similarly has recognized this as a refinement that makes better use of the dose-response evidence available than do calculations based on NOAELs.

The NOEL approach depends heavily on a single chosen dose level used in a study, and how closely it is placed relative to the next highest dose. The NOEL approach treats small and large studies the same, even though small studies, with their limited number of subjects, are less likely than large studies to find health effects at any given dose. In this case, the small group sizes in the Greer *et al*. (2002) study make it more difficult to detect an effect. For these reasons reliability of the NOEL approach can vary depending on the size of the study. In contrast, the BMD approach provides a systematic method for calculating a dose at a low specific effect level. The BMD approach uses all the dose-response evidence in the study, incorporates the shape of the dose-response curve, and takes into account the number of subjects in the study, thus providing a more reliable calculation. The advantages of using the BMD approach for this PHG are particularly important given the limited number of subjects that participated in the Greer *et al*. (2002) study.

Identifying Infants as a Sensitive Population

OEHHA, as part of its periodic review of perchlorate, assessed exposure patterns in bottle-fed infants as well as the special susceptibility of infants and children. OEHHA determined that infants, along with pregnant women and fetuses, are likely to be more susceptible to the effects of perchlorate.

The major change in the current PHG calculation relates to the updated information on infants as a sensitive population. OEHHA's review and updating of the perchlorate PHG considered the data from several human studies published after the 2004 PHG and the 2005 NAS review. These studies provided qualitative support for recognizing that infants are likely to be significantly more susceptible to perchlorate than healthy adults. Evidence for this includes the following:

1. New data suggest that many infants may not be receiving adequate iodine in their diets. In a study of nursing mothers in Boston, 47 percent of breast milk samples did not contain enough iodine to meet the infant iodine intake recommended by the Institute of Medicine (Pearce *et al.,* 2007). Perchlorate-related toxicity is likely to be greater in infants who are already deficient in iodine.
2. OEHHA's analysis of data from studies conducted in California and elsewhere provide evidence that thyroid hormone levels in infants were adversely affected by perchlorate at exposure levels that were much lower than the levels shown to cause no effects in healthy adults (Kelsh *et al.,* 2003; Brechner *et al*., 2000; Buffler *et al.,* 2006; Steinmaus *et al*., 2010; Li *et al.,* 2000a; Crump *et al.,* 2000).
3. Young infants have low stores of thyroid hormone (less than one day's worth, compared to several weeks' worth in adults) (van den Hove *et al*., 1999). Because of these low stores, infants may be less able to tolerate transient periods of decreased iodide uptake and decreased thyroid hormone production compared to adults.
4. Human data suggest that perchlorate can interact with other contaminants to produce a greater effect than that caused by perchlorate alone (Blount *et al*., 2006; Steinmaus *et al*., 2007), and infants are exposed to these same contaminants.

In the 2004 PHG, an uncertainty factor of 10 was applied to address all sensitive groups (pregnant women, lactating women, thyroid compromised adults) except infants, where an uncertainty factor of 3 was used. However, given the evidence discussed above, the extent and ways infants are likely to be more susceptible to perchlorate than healthy adults, and the fact that the Greer *et al.* (2002) study included only healthy adults, OEHHA has increased the uncertainty factor applied to infants from the factor of 3 used in the 2004 PHG to a factor of 10 in this updated PHG. This is one factor that resulted in the lowering of the updated PHG. The other factor driving the change in the PHG value is the use of updated drinking water intake rates for infants, described below.

Water Consumption by Infants

The water consumption rate by infants is one of the factors that influence the final PHG. The recent analysis by OEHHA (2012) of data available from a large survey of food and beverage intake conducted by the U.S. Department of Agriculture shows that drinking water intakes per kilogram of body weight are higher in infants than previously thought. This means that infants are likely to have greater perchlorate exposure per kilogram of body weight for a given concentration of perchlorate in drinking water than was estimated in the 2004 PHG.

OEHHA used its new analysis and chose the 95th percentile drinking water intake rate instead of an average rate in order to protect the infant population,

and not just those with average drinking water consumption. Infants who drink more water will have a greater exposure to perchlorate and thus may be at greater risk. In this case the bottle-fed infant will have the greatest intake of water and exposure to water contaminants.

The 95th percentile value of 0.237 L/kg-day for drinking water intake per body weight for infants aged 0-6 months (OEHHA, 2012) was used in the PHG calculations. For comparison, U.S. EPA (2009) typically assumes that infants and children drink 1 liter (L) per day and that they weigh 10 kilograms, that is 0.1 L/kg-day. Using the U.S. EPA value would result in a PHG of 2.7 ppb instead of 1 ppb.

Comparison with Other Agencies

Currently, there is no federal drinking water standard (MCL) for perchlorate. The current California MCL is 6 ppb. Several other states have action levels or MCLs in the range of 1-26 ppb as shown in the table below.

Table 48. State MCLs or Advisory Levels (ppb) for Perchlorate (ASTSWMO, 2011)

Alabama	24.5	Missouri	10.9
Alaska	26	New Jersey	5
Arizona	14	New Mexico	1
California	1 (PHG) 6 (MCL)	New York	5
Florida	4	Nevada	18
Hawaii	25	North Carolina	2
Kansas	10.9	Texas	17
Maine	1	Vermont	2 (prevent) 4 (enforce)
Maryland	1	Virginia	15
Massachusetts	2	Wisconsin	1 (prevent) 0.1 (enforce)

PHGs published by OEHHA are for use by the California State Water Resources Control Board (SWRCB) in establishing primary drinking water standards, that is, the California MCLs. In developing the PHG for perchlorate, OEHHA's approach follows that used by the NAS (2005) to develop its reference dose in several key areas:

1. Both OEHHA and NAS identified the Greer *et al.* (2002) human study as the critical study for evaluating the effects of perchlorate.
2. Both OEHHA and NAS chose iodide uptake inhibition in the Greer *et al.* (2002) study as the key effect on which to base their calculations.
3. Both OEHHA and NAS noted that the subjects in the Greer *et al.* (2002) study were healthy adults and concluded that some people may be more

susceptible to perchlorate than these healthy adult subjects. For this reason, both OEHHA and NAS applied an uncertainty factor of 10 to calculate a dose that would address inter-individual variability among humans and be protective of those who are likely to be sensitive to the effects of perchlorate.

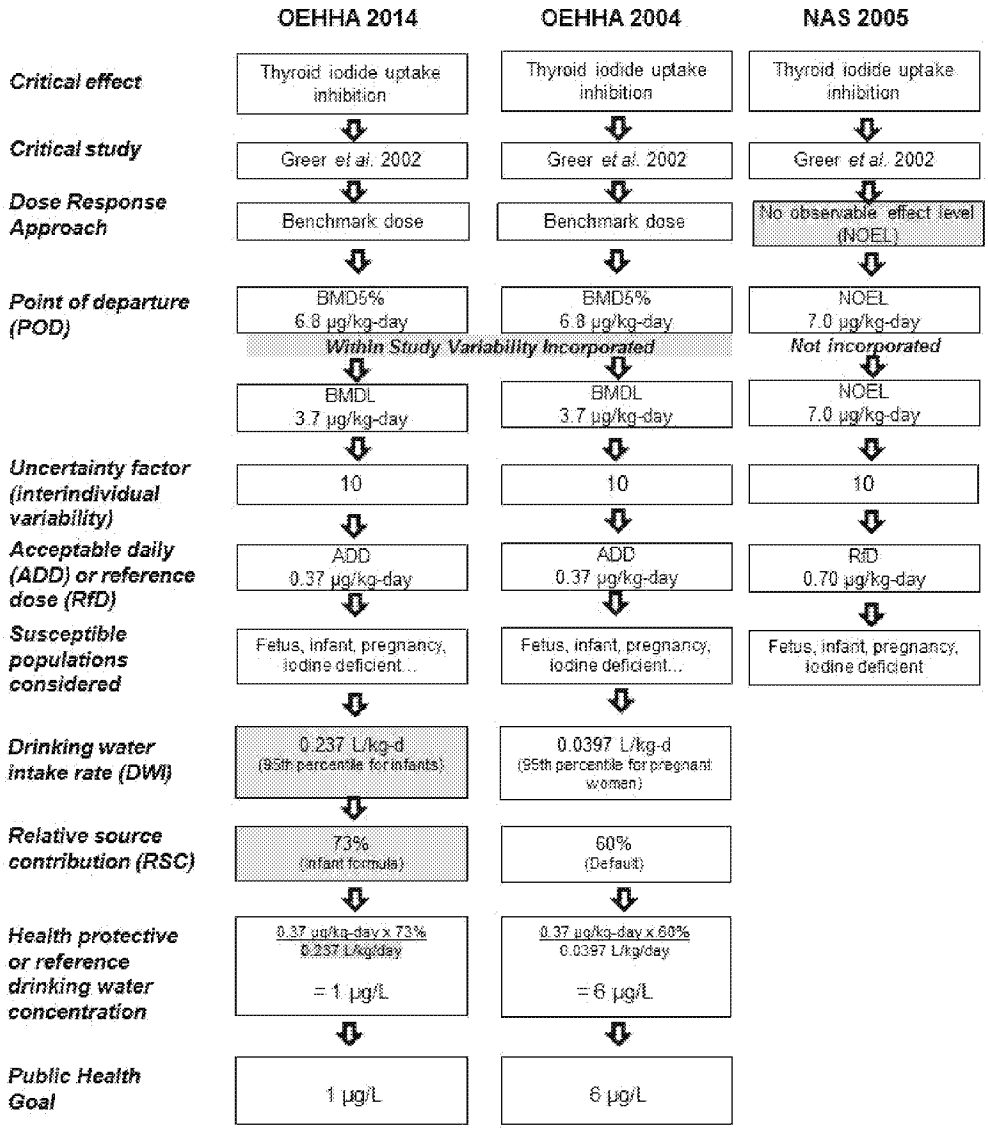
4. Both OEHHA and NAS identified the same populations likely to be more sensitive to perchlorate exposure: fetuses, preterm newborns, infants, developing children, pregnant women, people who have compromised thyroid function resulting from conditions that reduce thyroid hormone production, and people who are iodine-deficient.

There is only one substantive difference between the OEHHA and NAS analyses. The NAS used the no-observed-effect level (NOEL) approach. They determined that the NOEL was 0.007 mg/kg-day, the highest dose in the Greer *et al*. (2002) study that was not associated with a statistically significant response. OEHHA used the Benchmark Dose (BMD) approach and calculated a point of departure of 0.0037 mg/kg-day. As discussed above, the BMD method is a statistical method that is now widely recognized as a better approach because it incorporates more dose-response information from the study than the NOEL method (NAS, 2009; U.S. EPA, 2012).

From the NOEL, the NAS calculated a reference dose of 0.0007 mg/kg-day (the NOEL divided by the uncertainty factor of 10). OEHHA similarly calculated an ADD of 0.00037 mg/kg-day (the BMD-derived point of departure divided by the same10-fold uncertainty factor). Thus the two approaches differ by less than a factor of 2. The NAS did not take the next step to calculate an acceptable drinking water level for perchlorate.

A comparison of the NAS methods to those of this PHG and OEHHA's 2004 perchlorate PHG are shown in Figure 13.

Figure 13. Comparison of the Methods Used to Calculate OEHHA's Current and 2004 Perchlorate PHGs with the Methods Used by NAS (2005)



Conclusion

The primary toxic mechanism of perchlorate is a reduction in iodide uptake into the thyroid gland. If severe enough, this can lead to reduced thyroid hormone production. Adequate supplies of thyroid hormone are vital for a variety of physiologic processes, and even small reductions in thyroid hormone have been associated with increased cardiovascular disease risk factors, abnormal fetal brain development, and altered childhood cognition. The purpose of this updated PHG of 1 ppb is to identify a level of perchlorate in drinking water that prevents perchlorate-related reductions in thyroidal iodide uptake and subsequent decreases in thyroid hormone production that may be associated with any of these adverse health effects.

APPENDIX 1: ALTERNATIVE BENCHMARK DOSE CALCULATIONS USING BLOUNT *ET AL.*, 2006 DATA

Study Description

Blount *et al.* (2006) was a cross-sectional study of urinary perchlorate levels and serum levels of thyroid hormones in 2,299 men and women ≥ age 12 who took part in the 2001-2002 National Health and Nutrition Examination Survey (NHANES). NHANES was conducted by the National Center for Health Statistics of the Centers for Disease Control and Prevention (CDC) and was designed to assess the health and nutrition status of the non-institutionalized population of the U.S. This survey involved a complex multistage sampling design with some over-sampling in certain areas and among certain subgroups, but was designed to provide results that are nationally representative. Information that was collected as part of this survey included questionnaire data on demographic information, smoking, health history, and medication use. A single serum measurement of T4 and TSH and a single measurement of urinary perchlorate and iodine concentration were also collected. Other information collected included urinary creatinine, thiocyanate, and nitrate; and serum levels of albumin, cotinine, and c-reactive protein.

The authors assessed the relationship between serum thyroid hormone levels and urine perchlorate concentrations using a linear regression analysis adjusted for potential confounding variables and co-variates including age, urinary creatinine, estrogen use, c-reactive protein, cotinine, ethnicity, menopause, premenarche, pregnancy, fasting time, body mass index, and kilocalorie intake. Several factors including urinary perchlorate and creatinine and serum TSH were logarithm transformed to normalize their distributions. Exclusions included subjects with missing data on co-variates, a history of thyroid disease, current use of thyroid medications, extreme values of T4 or TSH (n = 3), and subjects missing perchlorate measurements.

No association was found between T4 or TSH and perchlorate in men. In women, separate analyses were done for urinary iodine levels above and below 100 µg/L. This level was chosen since it is used by the World Health Organization to define iodine deficiency in a population. Thirty-seven percent of the women in this study had urinary iodine levels below 100 µg/L. The results of the analyses in women are shown in Table A1. A statistically significant association was seen between increasing TSH and increasing perchlorate in women with iodine levels above and below 100 µg/L. A statistically significant association was also seen between decreasing T4 and increasing perchlorate in women with urinary iodine levels below 100 µg/L but not in women with iodine levels above 100 µg/L.

Table A1. Associations between Thyroid Hormone Levels and the Logarithm of Urinary Perchlorate in Women with High and Low Levels of Urinary Iodine (Blount *et al.*, 2006)

	N	β	SE	p-value
Urine iodine < 100 µg/L				
T4	348	-0.8917	0.1811	<0.0001
Logarithm of TSH	356	0.1230	0.0373	0.0010
Urine iodine ≥ 100 µg/L				
T4	724	0.2203	0.3687	0.5503
Logarithm of TSH	697	0.1137	0.0506	0.0249

Abbreviations: β, regression coefficient; N, number of subjects, SE, standard error of the regression coefficient.
Differences in the numbers of subjects with an iodine category are due to differences in the number of subjects missing data on co-variates in each analysis. Except for perchlorate and creatinine, only co-variates with p-values < 0.10 were retained in each model.

Selection of the Key Biochemical Effect, Critical Study, Benchmark Response (BMR), and Control Group

Defining the Key Biochemical Effect

Thyroid hormone. As discussed in the previous sections, perchlorate has been associated with a variety of health and physiological effects. Focus is placed on perchlorate's impacts on the thyroid gland for the following reasons:

- These effects have been reported at lower exposure levels than the other significant health effects associated with perchlorate. By preventing low-dose thyroid effects, these other effects should also be prevented.
- Thyroid hormone is a very important hormone for homeostatic control in humans and alterations in thyroid hormone production have been associated with serious adverse outcomes, including diminished cognitive development and IQ in children and increased cardiovascular disease risk factors in adults.
- As discussed below, detailed dose-response data on perchlorate and thyroid hormone levels meeting the major tenets of causal inference are available from Blount *et al.*, 2006.

Is this adverse? While some people may not consider decreased T4 or increased TSH to be an "adverse" health outcome in isolation, as detailed in the PHG document, decreases in T4 are very closely associated with outcomes that are clearly adverse such as childhood cognitive development and alterations in lipid metabolism (which are closely linked to cardiovascular diseases).

Statistically significant dose-response relationships have been seen between T4 and each of these outcomes in studies which involve at least some subjects with T4 or TSH values at levels traditionally considered to be within normal reference ranges (discussed in previous sections).

Selecting the Critical Study

The data on women with urinary iodine levels below 100 µg/L evaluated in Blount *et al.* (2006) and collected as part of NHANES 2001-2 were used for the point of departure calculations. These data showed a clear, statistically significant dose-response relationship in a group of subjects that are an essentially representative sample of all subjects ages 12 years and older in the U.S. Because this is basically a representative sample, the levels of perchlorate exposure seen in this group are likely to be those commonly found in the general U.S. population. Other reasons for selecting this study include:

- Its relatively large sample size, which helps ensure adequate statistical power.
- Its inclusion of a relatively large number of people who are potentially susceptible to perchlorate (i.e., women with low iodine intake). Other clinical dosing or occupational studies did not specifically examine susceptible groups. Using these other studies could therefore underestimate effects in susceptible populations.
- It is a human rather than an animal study.
- The individual data are publicly available.
- The findings linking perchlorate to thyroid effects are consistent with the major tenets of causal inference (reviewed in earlier sections).

In the NHANES 2001-2 dataset, the association between T4 and perchlorate was particularly strong in women with both low iodine levels and high thiocyanate levels (Steinmaus *et al.*, 2007). OEHHA did not use the high thiocyanate group for our dose-response analysis since it involved only a relatively small number of subjects (n = 78).

Using raw data from NHANES: The main outcome variables in the Blount *et al.* (2006) study are serum levels of T4 and TSH. Levels of these hormones, as well as urinary levels of perchlorate and data on numerous potential co-variates are available for each individual in the study on the NHANES website. Since these data are publicly available OEHHA performed its own calculations using the individual data rather than relying on the grouped data and final results presented by Blount *et al.* (2006). As we have shown, the results of our analyses (Steinmaus *et al.*, 2007) are very similar to those of Blount *et al.* (2006). The minor differences are probably due to differences in the statistical packages used and differences in the way certain potential co-variates were defined. Performing

the calculations with the raw data allowed OEHHA to confirm the statistical analyses of Blount *et al*. (2006) and allowed a more thorough evaluation of specific aspects of causal inference (presented previously).

The Benchmark Dose Approach

The benchmark dose (BMD) approach was used to calculate a point of departure (POD). The advantages of this approach over the NOAEL approach are discussed elsewhere (U.S. EPA, 2000). The BMD is defined as the dose (or exposure) that causes a prescribed response rate (Crump, 2002). A statistical lower bound of the BMD, usually the 95% lower confidence limit (the BMDL), is used as the point of departure for defining an exposure level that is likely to be without an appreciable risk of deleterious effects in humans. Using the BMDL rather than the BMD helps to account for the uncertainty inherent in a given study and according to the U.S. EPA, "assures (with 95% confidence) that the desired response is not exceeded (U.S. EPA, 2000)." The BMD and BMDL are calculated by fitting a mathematical model to dose-response data and determining the dose, and its 95% CI, that is associated with a predefined benchmark response (BMR).

BMD for continuous data. In the past, the BMR has been typically defined as a 10 percent increase in the proportion of subjects exhibiting a predefined adverse response over the baseline response (the proportion exhibiting the response in a control or unexposed group). The 10 percent level is based primarily on the level of response that can be detected with sufficient statistical power in typical sized animal and human studies. Benchmark dose calculations can also be done for response data that are continuous. The 2004 OEHHA perchlorate PHG, which used a 5 percent decrease in radioactive iodide uptake, is an example of using a response variable that is continuous.

Selecting the BMR

Several approaches can be used to define a BMR:

An absolute level of T4 that is generally considered to be adverse: There is no single value of T4 or TSH that most clinicians would consider to define "adverse." Sometimes, the upper and lower 2.5th percentiles of T4 values collected in large population samples like NHANES have been used to define "normal" reference ranges. However, these levels are not absolute: some people with T4 levels outside these reference ranges will not exhibit thyroid disease, while some with T4 values within the normal reference range will. As discussed in the PHG document, several studies have shown linear associations between T4 and disease-related markers at T4 values well within normal reference ranges. For these reasons, there is no single absolute value of T4 which can be used to separate those likely to have significant risks of thyroid-related disease from those likely to have no risk of disease. Regardless, T4 percentile cut-off points are related to the risks of thyroid disease. That is, at least at the lower spectrum of T4 levels, the lower the percentile a subject's T4 value falls into, the greater

their risk of thyroid-related disease. Because of this, OEHHA evaluated the use of various percentiles of T4 in NHANES (the lower 2.5th, 5th, and 10th percentiles) as cutoff points for defining people likely to have a substantial risk of thyroid-related disease. This is discussed in further detail below.

Dichotomizing the data: One way of defining a BMR would be to dichotomize the outcome data; that is, define a serum level below which T4 would be considered adverse and above which it would not be considered adverse. As mentioned above, this could be defined as the lower 2.5th or 5th percentiles of T4 levels in a large population sample. Once dichotomized, the BMR can then be defined as an increase of 10 percent in the proportion of subjects that exhibit T4 levels below this cut-off point compared to the proportion seen in an unexposed (or relatively unexposed) control group. The problem with this approach is that much of the detailed information that is part of the continuous data set is lost, with a potential reduction in statistical power. The hybrid approach discussed below is one method for overcoming this problem.

Absolute or percentage change: Another approach for defining a BMR is to use a level of change in T4 that is generally considered to be biologically significant. For example, a 10 percent decrease in T4 from the mean T4 of an unexposed control group might be considered to be an important change. The BMD would then be the perchlorate dose associated with this 10 percent decline in T4. One problem with this method is that there is no single level of change in T4 that is universally accepted as being adverse or important.

Any change or any detectable change: Given the linear relationship between T4 and lipid metabolism and the linear relationship between T4 and childhood cognition that may occur within normal ranges of T4, it might be suggested that *any* decrease in T4 should be considered important. This is especially relevant on a population basis where any measurable decrease in population mean T4 would likely cause an increase in the number of people with T4 levels in the adverse range. For this reason, OEHHA evaluated the possibility of defining a BMR as a relatively small decrease in T4 (e.g., 1 percent and 5 percent) from the mean T4 in an unexposed control group. The problem with this method is that the selection of 1 percent or 5 percent could be considered arbitrary. In other words, one might ask why a 0.5 percent decrease or a 0.0001 percent decrease was not selected.

Because of this, OEHHA considered another approach: defining a BMR as any decrease in T4 that is detectable statistically. This is similar (albeit not the same) to the BMR approach used for outcome data that are dichotomous, where the BMR is typically defined as an increase of 10 percent in the proportion of subjects eliciting a predefined adverse effect. The value of 10 percent is used because it is the level of response that can be seen with sufficient statistical power in study designs and sample sizes commonly used in animal and human studies (U.S. EPA, 2000). Standard sample size calculations (Hulley and Cummings, 1988) and the variance in T4 seen in the 385 women with low iodine

in NHANES 2001-2 were used to estimate the change in T4 that is likely to be detectable with sufficient statistical power in this group of women. OEHHA's calculations suggest that a study this size would have 86 percent power to detect about a 10 percent decrease in mean T4 comparing a group the size of the lower 10^{th} percentile (i.e., 38 subjects) to the remaining subjects (i.e., 385 – 38 = 347 subjects). This power is close to the 80 percent level that most researchers would consider minimally adequate. The lower 10^{th} percentile was used in these calculations because subjects in the lower 10^{th} percentile of urine perchlorate were used as the "unexposed" control group in the BMD calculations (discussed below). Based on these statistical power estimates, a 10 percent decrease in mean T4 was selected as the BMR, although other levels of BMR were assessed for comparison purposes.

Selecting an Unexposed or Lesser Exposed Control Group

Since all of the subjects in NHANES 2001-2 had detectable levels of perchlorate, there is no truly unexposed group. Because of this, the following methods for defining a control group were considered:

a. *Lowest detected dose:* One method is to use the lowest dose detected as the baseline or control dose (0.19 µg/L). The problem with this method is that the control T4 level would be based on only one subject (only one of the 385 low iodine women had a urine perchlorate level of 0.19 µg/L) and therefore it would not be appropriately robust.

b. *Predicted T4 for the lowest detected dose:* Another method is to use the regression model to predict a mean T4 expected for a perchlorate dose of 0.19 µg/L. Since this T4 estimate is essentially based on the regression model (and all of the data that went into it), it would be more robust. The problem with this method is that the control group mean T4 would be based on a model prediction rather than on an actual set of real values.

c. *Predicted mean T4 for a perchlorate level of zero.* Another method would be to use the regression model and enter perchlorate as zero. The problem with this method is that the model includes the logarithm of perchlorate (log-perchlorate) and there is no logarithm of zero.

d. *A log-perchlorate of zero.* Another method could be to use the regression equation to estimate a mean T4 at a log-perchlorate of zero. The problem with this method is that a log-perchlorate of zero corresponds to a perchlorate level of 1 µg/L, and there is no obvious rationale for using a urinary concentration of 1 µg/L as the control level.

e. *Actual data.* The other option evaluated was using actual data from the low iodine women in NHANES 2001-2 and defining the control group as those subjects below a particular percentile cut-off point for perchlorate dose. Subjects with perchlorate values in the lower 5^{th}, 10^{th}, and 20^{th} percentiles of

creatinine-adjusted urinary perchlorate concentrations were used for this. It was decided to use a control group defined as those subjects in the lowest 10th percentile of creatinine-adjusted perchlorate residuals. This was chosen because: 1) the lower 10th percentile was the basis of the statistical power calculations used to define the BMR of 10 percent (described above); 2) it was necessary to categorize perchlorate into ten equal size dose groups in order to use these data in the BMDS (described below).

The Standard Deviation and Hybrid Approach

One standard deviation (SD): The U.S. EPA suggests in the absence of any other idea about what level of response to consider adverse, a change in the mean of the outcome (T4) equal to one standard deviation from the control mean can be used (U.S. EPA, 2000). They also recommend that regardless of what approach is used, the standard deviation approach be presented for comparison. Crump and others have shown that for a response variable that is normally distributed, a decrease of one SD corresponds to an increase of about 10 percent in the proportion of subjects falling below the 2nd percentile value of an unexposed comparison group (Crump, 1995).

Hybrid approach: The hybrid approach uses the distribution of a continuous variable (i.e., a mean T4 and its standard deviation) to estimate the proportion of subjects falling below a predefined percentile cutoff point (Gaylor and Slikker, 1990; Crump, 1995). This is done by converting the mean T4 in the unexposed group and the BMR into units on the standard normal deviation scale.

Crump and others present a method for determining the fraction of the standard deviation of the mean outcome value (i.e., T4) that corresponds to a particular proportion of subjects that fall below (or above) a particular percentile cutoff point. For example, if a T4 value below the 2.5th percentile in an unexposed control population is considered adverse, then a decrease in T4 corresponding to 0.82 times the T4 standard deviation corresponds to a BMR of 10 percent (i.e., a 10 percent increase in the proportion of people that will fall below the 2.5th percentile cut-off point). The equation is:

$$BMR = Q \times SD, \text{ where}$$

$$Q = N^{-1}[1-P(0)] - N^{-1}[1-P(0) - BMR]$$

N^{-1} is the inverse of the standard normal distribution (i.e., the z-score for the probability of 1-P(0) or 1-P(0)-BMR), and P(0) = the percentile below which is considered adverse (e.g., P(0) = 0.025 if being below the 2.5th percentile is considered adverse).

The Hybrid Approach Calculations

Standard deviations: The standard deviation in T4 for the 385 low iodine women in NHANES 2001-2 in the lower 5th, 10th, and 20th percentiles of creatinine-

adjusted perchlorate residuals were 1.87, 1.86, and 1.72, respectively. The similarity of these numbers shows that the variance in T4 is essentially independent of perchlorate dose.

Calculating Q. Values of Q were calculated for several levels of P(0) and BMR. Values for P(0) corresponding to the lower 2.5th and 5th percentiles of T4 were used since these have traditionally been used to define the lower bounds of "normal" T4 reference ranges. A P(0) value corresponding to the lower 10th percentile was also evaluated since significant cognitive effects were seen in children in the lowest 10th percentile of T4 or fT4 (Pop *et al.*, 1999, 2003: Kooistra *et al.*, 2006). BMRs of 5 and 10 percent were chosen since 5 and 10 percent are thought to represent levels that can be detected statistically in typical sized animal and human studies (U.S. EPA, 2000). Values of Q for these levels of BMR and P(0) are shown in Table A2.

Table A2. Hybrid Table: Calculating Values of Q

T4 considered adverse	P(0)	1-P(0)	N_A^{-1}	BMR	1-P(0)-BMR	N_B^{-1}	Q
< 2.5th percentile	0.025	0.98	1.960	5%	0.93	1.440	0.52
	0.025	0.98	1.960	10%	0.88	1.150	0.81
< 5th percentile	0.05	0.95	1.645	5%	0.90	1.282	0.36
	0.05	0.95	1.645	10%	0.85	1.036	0.61
< 10th percentile	0.1	0.90	1.282	5%	0.85	1.036	0.25
	0.1	0.90	1.282	10%	0.80	0.842	0.44

Abbreviations: BMR, the benchmark response or the increase in the proportion of people who fall below the T4 level considered adverse; N_A^{-1}, standard normal deviate for 1-P(0); N_B^{-1}, standard normal deviate for 1-P(0)-BMR; P(O), the percentile of T4 in the control group below which would be considered adverse.

Benchmark Dose Calculations

Transforming NHANES 2001-2 Data for the BMDS

The U.S. EPA BMD software (BenchMark Dose Software (BMDS) version 2.0) was used for the POD calculations. The following data transformations were required:

Creatinine adjustment: The BMDS does not allow the use of co-variates such as urine creatinine concentration. As shown above, urine creatinine was the only individual co-variate that caused a greater than 10 percent change in the perchlorate-T4 regression coefficient (Table 39). Because the addition of urinary creatinine appears to improve the model, it was decided that this variable should be incorporated into the POD calculations. This was done by calculating creatinine-adjusted perchlorate residuals ("perchlorate residuals") using the Proc

Reg statement in SAS with the logarithm of urinary perchlorate concentration (log-perchlorate) as the dependent variable and the logarithm of urinary creatinine concentration as the independent variable (logarithm of creatinine or log-creatinine). The association between serum T4 and the creatinine-adjusted perchlorate residuals was only slightly different than the association seen in the fully adjusted model.

OEHHA considered using the urine perchlorate:creatinine ratio. However, the association between T4 and this ratio in the low iodine women was not as strong as when perchlorate residuals were used and was only borderline statistically significant (unadjusted regression coefficient between T4 and the perchlorate:creatinine ratio = -1.18; SE = 0.66; p = 0.07). This is likely due to the factors discussed previously for the iodine/creatinine ratio. That is, it creates a variable that is not only dependent on perchlorate, but also on all the factors that determine an individual's urinary creatinine level (e.g., muscle mass, diet, physical activity, and many other factors). Including all these other influences into the perchlorate exposure variable can lead to misclassification of true perchlorate exposure.

Other co-variates and potential modifying factors: None of the other co-variates used in Blount *et al.* (2006) caused important changes in the perchlorate-T4 regression coefficient so these were not used in the BMD calculations. In addition, the NHANES complex sampling weights were not used because they had only a small impact on regression coefficients and their standard errors (Table A3), and the incorporation of these weights would have significantly complicated the model.

Table A3. T4-Log-Perchlorate Regression Coefficients Using Different Methods of Analysis

Method	Adjusted	Weights[a]	β	SE	p
Blount *et al.*, 2006	Full	Yes	-0.89	0.18	<0.0001
Steinmaus *et al.*, 2007	Full[b]	Yes	-0.73	0.22	0.004
	Full[b]	No	-0.87	0.27	0.0016
	Creatinine Only	No	-0.81	0.27	0.0026
	Unadjusted	No	-0.67	0.23	0.0041
BMDS	Creatinine Only	No	-0.79	0.28	na[c]

Abbreviations: BMDS, benchmark dose software; β, regression coefficient; SE, standard error; na, not available.
[a]NHANES sampling weights applied
[b]Only independent variables with p-values < 0.20 were entered and retained in the model except for log-creatinine which was retained in the model regardless.
[c]p-value not given. The 95% CI of the regression coefficient is -1.34 to -0.24

Figure A1 shows the linear relationship between serum T4 and the creatinine-adjusted perchlorate residuals. The effects of possible outlying values were assessed by removing certain data points. Removing the leftmost point in this figure (T4 = 10.1 µg/dL, urine perchlorate = 0.24 µg/L, urinary creatinine = 146 mg/dL) changed the regression coefficient from 0.8122 to 0.7924. Removing the rightmost data point in this figure (T4 = 7 µg/dL, perchlorate = 100 µg/L, creatinine = 40 mg/dL) changed the regression coefficient from 0.8122 to 0.8135.

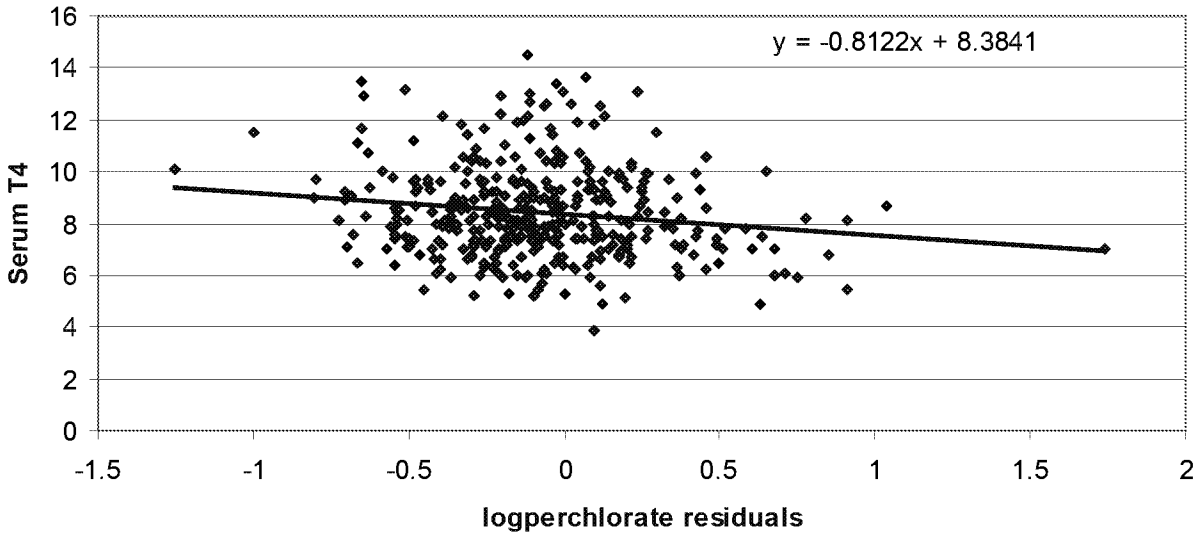

Figure A1. Serum T4 and Creatinine-adjusted Perchlorate Residuals in 385 Women with Urinary Iodine Levels < 100 µg/L, NHANES 2001-2

Categorizing dose: The BMDS allows for the use of individual data on dose and response and both can be entered as continuous variables. In controlled human trials, such as the Greer *et al*. (2002) study, doses are usually categorized into a relatively small number of dose groups. In NHANES 2001-2, each individual subject had their own urinary perchlorate concentration. Since there were 385 subjects in this study, this resulted in hundreds of "dose groups." Entering this many dose groups into the BMDS led to implausibly wide confidence intervals around the BMD and implausibly low BMDL values. To make the calculations computationally easier, perchlorate residuals were ranked into 10 equal sized dose groups and each individual in each group was assigned the mean perchlorate residual value for that group. Categorizing data into groups such as these can potentially cause a loss of information and decrease study power but this did not seem to be the case here. Table A4 compares the perchlorate-T4 model parameters calculated in SAS Proc Reg using the individual data versus those calculated by the BMDS using the 10 dose groups. As seen, the regression coefficient and its standard error are essentially the same in both models. This shows that using the 10 dose groups instead of the 385 individual dose points resulted in little loss in statistical power and essentially no loss in our ability to accurately measure the dose-response relationship.

Since the choice of using 10 dose groups was somewhat arbitrary, the effect of using more or fewer dose groups was evaluated. Table A4 shows the results of the BMDS calculations using 5 or 20 equal size dose groups. As seen, when five dose groups were used it appears that too much information was lost and the dose-response relationship becomes less strong. Using 20 dose groups didn't substantially change the model compared to when 10 groups were used.

Table A4. Association between T4 and Perchlorate Residuals: Comparing Individual Data to Dose Groups

Method	Intercept (SE)	β (SE)
SAS Proc Reg: individual data	8.04 (0.56)	-0.81 (0.27)
BMDS linear model:		
10 dose groups	8.88 (0.17)	-0.79 (0.28)
5 dose groups	8.68 (0.16)	-0.54 (0.30)
20 dose groups	8.99 (0.20)	-0.83 (0.27)

Abbreviations: β, regression coefficient; SE, standard error

Positive numbers for dose: The BMDS does not accept negative values for dose. The dose metric was perchlorate residuals, which had a mean of zero and some positive and some negative values. To prevent having any negative values for dose, the mean of the lowest dose group was subtracted from the means of each dose group to obtain a new dose variable for each group. This resulted in a value of zero for the lowest dose group and positive values of dose for all other groups. Since this maintained the absolute difference between doses it did not affect the perchlorate-T4 residual slope or its standard error.

Following these transformations, BMDS was used to calculate a BMD and BMDL. The BMD and BMDL are the creatinine-adjusted logarithm of urine perchlorate residuals minus the perchlorate residuals in the lowest dose group. These numbers were converted back into a urinary perchlorate level in µg/L using the following steps:

1. Adding the mean perchlorate residual in the lowest dose group (note that this is actually a negative number so adding it is the same as subtracting its absolute value). This gives the creatinine-adjusted residuals of the logarithm of urine perchlorate concentration.

2. Because the residuals have a mean of zero, and some positive and some negative values, they have no practical meaning in terms of an actual perchlorate concentration. To convert the residuals back to an actual value of log perchlorate, the log-perchlorate concentration that was predicted for the mean log-creatinine level of the study population as a whole was added using the method recommended in Willett and Stampfer, (1998). The predicted log-perchlorate concentration was calculated using SAS Proc Reg with log-perchlorate as the dependent variable and log-creatinine as the independent variable (the same equation used to calculate the residuals).

3. This number was then converted to a urine perchlorate level in µg/L by taking the inverse log.

Using the BMDS

The linear model using the continuous data option was selected in the BMDS. The individual data for serum T4 was entered as the response variable and the mean values for each dose group (as described above) were entered as the dose variable. As discussed above, subjects in the lowest 10^{th} percentile of perchlorate residuals were used as the "unexposed" control group and had a transformed dose value of zero. The BMR was set at a relative decrease in T4 of 10 percent. Other options selected were: the constant variance and BMD calculation boxes were checked. Parameter assignments were all set at "default," the degree of polynomial was set at 1, the confidence level was set at 95%, and the adverse direction was set at "down."

BMDS Results

The following table shows the BMD and BMDL calculations where the BMR is defined as a 10 percent decrease in T4 from the mean T4 in the "unexposed" control group. For comparison purposes, BMD calculations are also shown for other definitions of BMR:

- The hybrid approach was used, with Q values corresponding to a 5 percent (Q = 0.25) or 10 percent (Q = 0.44) increase in the proportion of subjects below the lower 10^{th} percentile of T4 in the "unexposed" control group. The lower 10^{th} percentile was chosen because this was the cut-off used to define the "low" fT4 group in Kooistra *et al.* (2006), Pop *et al.* (1999), and Pop *et al.* (2003), three studies that found statistically significant associations between low maternal gestational fT4 and childhood cognitive deficits.

- Calculations are shown for BMRs defined as 20-30 percent decreases in T4 because this was the level of difference in T4 and fT4 associated with statistically significant declines in child cognitive development in other studies.

- Calculations for a BMR equal to a one standard deviation change in the mean T4 of the control group are shown because U.S. EPA recommends that these always be shown for comparison purposes.

Table A5. BMD and BMDL Results for Various Levels of BMR

BMR	1%	5%	10%	20%	30%	0.25SD[a]	0.44SD[a]	1SD
BMD (from the BMDS)	0.11	0.56	1.13	2.26	3.38	0.56	0.98	2.23
BMDL (from the BMDS)	0.07	0.37	0.73	1.46	2.19	0.35	0.62	1.40
Step 1: Add the lowest dose								
Lowest dose	-0.544	-0.544	-0.544	-0.544	-0.544	-0.544	-0.544	-0.544
BMDL log-perchlorate residual	-0.471	-0.179	0.186	0.916	1.647	-0.194	0.072	0.857
Step 2: Convert residual to log-perchlorate								
log-perc at mean log-creat	0.251	0.251	0.251	0.251	0.251	0.251	0.251	0.251
Add mean log-perc to residual log-perchlorate	-0.220	0.072	0.437	1.167	1.898	0.057	0.323	1.108
Step 3: Take inverse log								
BMDL in µg/L (urine)	0.60	1.18	2.73	14.69	78.99	1.14	2.11	12.83
Convert urine µg/L to intake								
Age[b]	35	35	35	35	35	35	35	35
Weight[b]	66.7	66.7	66.7	66.7	66.7	66.7	66.7	66.7
Height[b]	160.9	160.9	160.9	160.9	160.9	160.9	160.9	160.9
k (constant, for females)	1.64	1.64	1.64	1.64	1.64	1.64	1.64	1.64
Gram creatinine/day estimate	1.190	1.190	1.190	1.190	1.190	1.190	1.190	1.190
Creatinine g/L[b]	0.53	0.53	0.53	0.53	0.53	0.53	0.53	0.53
Intake at BMDL (in µg/day)	1.4	2.6	6.1	33.0	177.3	2.6	4.7	28.8
Intake at BMDL (in µg/kg-day)	0.020	0.040	0.092	0.495	2.659	0.038	0.071	0.432

[a]The T4 standard deviation (SD) in the control group was 1.87 so 0.25SD = 0.4675 and 0.44SD = 0.8228.
[b]The median levels in all 385 low iodine women in NHANES 2001-2 were used for these values.

Converting urinary perchlorate concentrations to levels of perchlorate intake

In all of these POD calculations perchlorate dose is expressed in terms of a urinary concentration of perchlorate. These values were used to calculate the BMD and BMDL. These were converted into an estimated daily intake of perchlorate using the method presented in Blount *et al.*, 2007. This method is based on equations from Crockcroft and Gault (1976) and modified by Mage *et al.* (2004) and estimates perchlorate intake using urinary perchlorate and creatinine concentrations combined with estimates of daily creatinine output which are based on age, height, gender, and weight. This equation is:

$$\text{Daily perchlorate intake} = \frac{\frac{\mu g \text{ urine perchlorate}}{\text{gram urine creatinine}} \times \frac{\text{gm creatinine}}{\text{Day}}}{\text{kg}}$$

Where gm creatinine / day is estimated by:

$10^{-6} \times k \times (140 - \text{age(year)}) \times \text{weight(kg)}^{1.5} \times \text{height(cm)}^{0.5}$

Where k = 1.64 for females. The median values in the 385 low iodine women were used for age (35), height (160.9 cm), weight (66.7 kg), and urine creatinine concentration (53 mg/dL). The results of these calculations are shown at the bottom of Table A5.

Summary

OEHHA calculated an intake BMDL of 0.092 µg/kg-day for a 10 percent decrease in T4. This BMDL is reasonably close to that calculated using the hybrid approach corresponding to an increase of 10 percent in the proportion of subjects with T4 values below the lower 10^{th} percentile. The BMDS graphical displays of both of these analyses are shown in Figures A2 and A3.

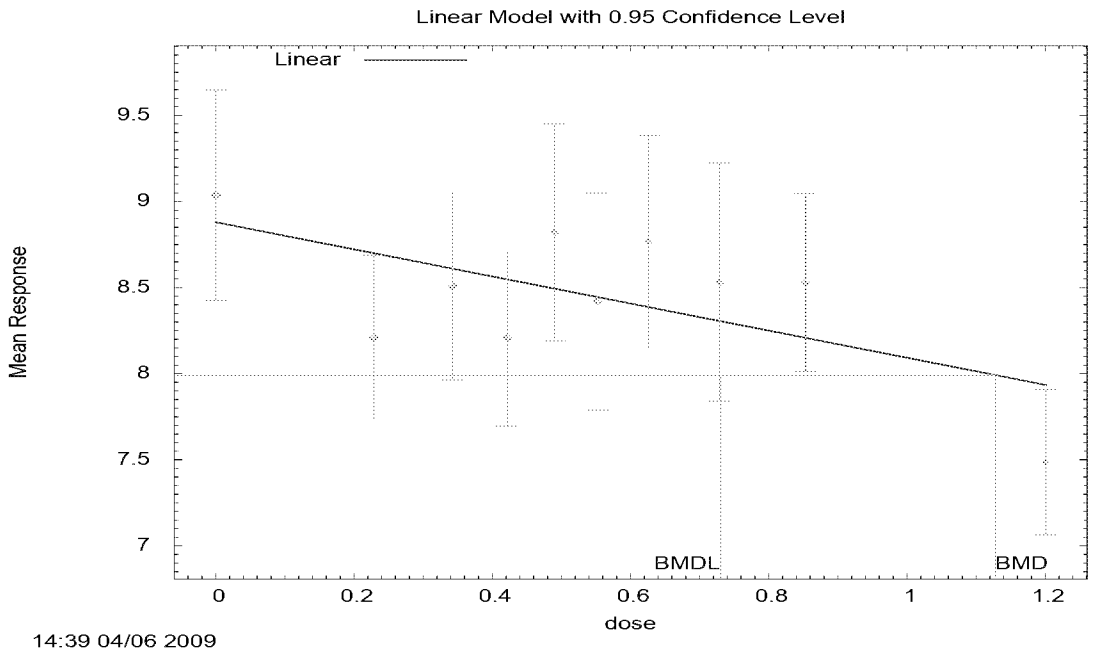

Figure A2. BMDS Output for Serum T4 (Mean Response) and Transformed Log Perchlorate Residuals (Dose) for a BMR of 10 Percent Decrease in T4

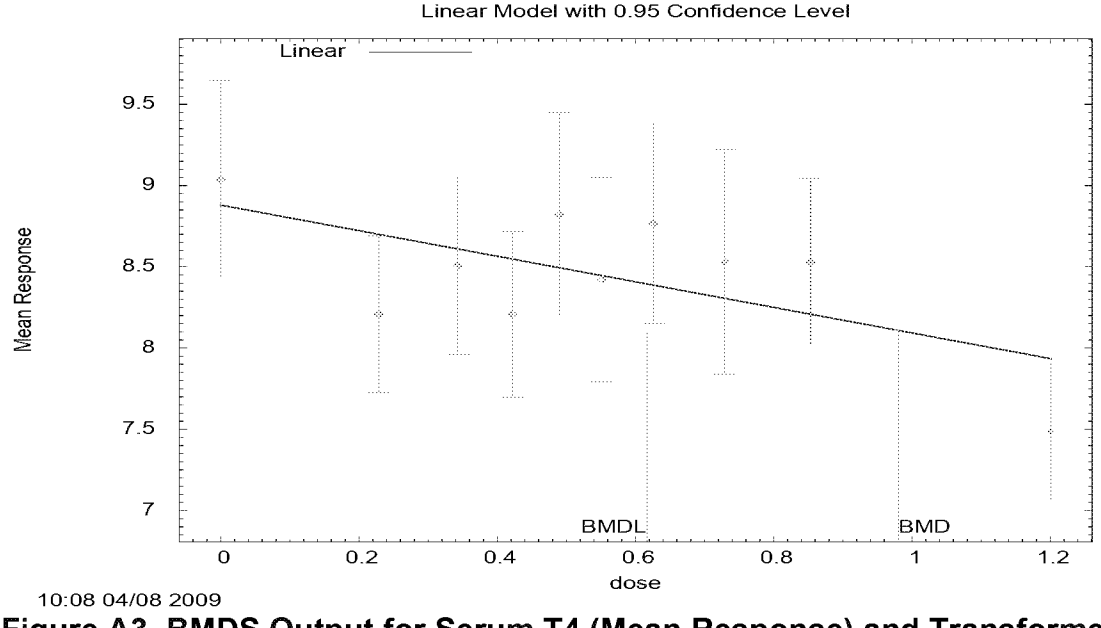

Figure A3. BMDS Output for Serum T4 (Mean Response) and Transformed Log Perchlorate Residuals (Dose) for a BMR of 0.44 x the T4 Standard Deviation of the Control Group

Calculation of the PHG Using NHANES 2001-2002 Data

Acceptable Daily Dose

For estimation of a health-protective concentration of perchlorate in drinking water, an acceptable daily dose (ADD) of the chemical from all sources will first be calculated. This involves incorporation of appropriate estimates of uncertainty in the extrapolation of the dose leading to the key biochemical effect from human or animal studies to the estimation of a lifetime ADD that is unlikely to result in or lead to any toxic effects. For this purpose, the following equation can be used:

$$\text{ADD} = \frac{\text{NOAEL/LOAEL/BMDL in mg/kg-day}}{\text{UF}}$$

where,

ADD = estimated maximum daily dose that can be consumed by humans for an entire lifetime without toxic effects;

NOAEL/LOAEL/BMDL = no-observed-adverse-effect level, lowest-observed-adverse-effect level, or lower limit on the benchmark dose estimated from the critical study;

UF = uncertainty factor(s).

For this case, the ADD is estimated from the lower limit of the two-sided 95 percent confidence interval of the perchlorate dose estimated to cause a 10 percent reduction in serum T4 levels, as observed in Blount *et al.* (2006). In this study, statistically significant associations between increasing perchlorate and decreasing T4 were seen in women with urinary iodine levels below 100 µg/L but not in women with higher iodine levels.

An uncertainty factor of four is used, including a factor of 2 to account for uncertainty due to the use of cross-sectional data to derive the dose-response estimates, and a factor of 2 to account for uncertainty due to possible increased susceptibility related to factors that were not already taken into account (e.g., exposure to other thyroid-inhibiting agents like thiocyanate, thyroid diseases, additional susceptibility in the fetus and young children). Thus,

$$\text{ADD} = \frac{0.092\ \mu\text{g/kg-day}}{2 \times 2} = 0.023\ \mu\text{g/kg-day}$$

Public Health Protective Concentration

Calculation of a public health protective concentration (C, in mg/L) for perchlorate in drinking water uses the following equation for noncarcinogenic endpoints:

C = ADD µg/kg-day × (BW/WC) × RSC

C = 0.023 µg/kg-day x 23.3 kg-day/L x 1

C = 0.54 µg/L = 0.5 µg/L (ppb) (rounded)

where:

(BW/WC) = the ratio of body weight (kg) and tap water consumption rate (L/day); the ratio for the 95th percentile of the pregnant woman population is estimated to be 0.0233 kg-day/mL or 23.3 kg-day/L (OEHHA, 2012 and Table 47 above); and

RSC = relative source contribution; a value of 1 is used for pregnant women. See the explanation for this value below.

Uncertainty factors

Susceptibility: Potential susceptible subpopulations were listed previously. It is likely that much of the susceptibility due to inadequate iodine intakes is already incorporated by using data on women with low iodine levels for these BMD calculations. In addition, some of the susceptibility due to several of the other factors listed above is likely already included in these calculations since NHANES is a population based study and involves at least some subjects who fall into the susceptible subgroups listed above. Because of this, OEHHA did not use the uncertainty factor of 10 that would typically be applied to account for inter-individual variability when dose-response data are derived from healthy individuals. However, some potentially susceptible groups were not included or were not specifically evaluated in the NHANES data set used. These include fetuses, infants and young children, people with thyroid diseases, and subjects exposed to high levels of other NIS inhibitors. An uncertainty factor was added to account for the potential susceptibility in these groups. Data from Steinmaus *et al.* (2007) suggest that the magnitude by which perchlorate reduces T4 levels is about 2 times greater in people with high thiocyanate levels than in people with average or low thiocyanate levels. Based on these findings an uncertainty factor of 2 was added, although it should be noted that the kinetics in rodents may be different than in humans, particularly with respect to the maternal-fetal transfer of chemicals.

Database weaknesses: An uncertainty factor was also added to account for the fact that this dose-response assessment is based on cross-sectional data. As discussed above, the single measurements of serum T4 and urinary perchlorate that were collected in NHANES 2001-2 may not be completely accurate measures of true long-term T4 levels or perchlorate exposure. Because this bias is most likely to be non-differential, the resulting impact on the perchlorate-T4 regression coefficient is likely to be towards a regression coefficient of zero, and true associations might actually be stronger than the one observed. Beaton *et al.* (1979) published an equation for predicting the magnitude of this bias:

$\beta_t = \beta_0 (1 + R^2_x/n_x)$,

where β_t is the estimated true regression coefficient after correcting for misclassification, β_0 is the observed regression coefficient, R^2_X is the ratio of intra- to inter-individual variances for the misclassified variable x, and n_x is the number of replicate measures of x per subject that were collected in the study. Since only a single urine and serum sample were collected from each subject in NHANES, $n_x = 1$, and the degree of bias is primarily related to R^2_x. Information on the value of R^2_x is not available in the NHANES 2001-2 data set, and OEHHA could not find a similar published study that specifically provided values of R^2_x for urinary perchlorate concentrations in humans.

In one study however, Ohira *et al.* (2008) compared 24-hour urine perchlorate measurements to creatinine-adjusted spot urine perchlorate concentrations in 14 breastfeeding mothers and reported that the average deviation between these two measures was 105 percent. In this NHANES study group, the mean spot urine perchlorate concentration was 2.86 µg/L. If one assumes the average deviation in the NHANES population was similar to that of Ohira *et al.* (2008), then the average deviation between a single spot urine perchlorate concentration and 24-hour sample concentrations in the NHANES study group would be about 3.0 µg/L (i.e., 105 percent x 2.86 µg/L).

Assume that:

1. The *mean* perchlorate concentration in spot samples from a large group of subjects (x_m) will be about equal to the *mean* perchlorate concentration in 24-hour samples from this same large group (this is probably a valid assumption because while a spot concentration may vary from a 24-hour concentration in any given individual, the spot concentration and 24-hr concentration means in the group should be about the same), and

2. The mean perchlorate concentration in 24-hour samples is a much better reflection of true perchlorate intake than perchlorate concentration from a spot urine sample (more on this later).

Then an estimate of the variance due to intra-individual variability associated with the use of spot samples might be estimated as:

Variance = $\sum (x_m - x_i)^2 / n - 1$,

where n is the number of subjects in the study, and $x_m - x_i$ is the average deviation between spot urine and 24-hour urine concentrations (3.0 µg/L). Given

this, the estimate of intra-individual variance is:

$$= 385 * (3.0\ \mu g/L)^2 / (385-1)$$

$$\approx 9\ \mu g/L$$

The total variance (intra- and inter-individual variance) in the spot urine perchlorate concentrations in the NHANES 2001-2 data set (all 385 low iodine women) was 32.9 µg/L. These data suggest that R^2_x might be somewhere near:

R^2_x = variance $_{\text{intra-individual}}$/variance $_{\text{inter-individual}}$

$$= 9\ \mu g/L / (32.9\ \mu g/L - 9\ \mu g/L) = 0.38$$

The corrected regression coefficient could be somewhere near:

$$\beta_t = \beta_0 (1 + R^2_x/n_x)$$

$$= 0.79 (1 + 0.38/1) = 1.09$$

That is, the corrected regression coefficient between perchlorate and T4 is about 1.09 times larger than the observed coefficient.

It should be noted that these calculations are estimates. They are based on the assumptions that 24-hour perchlorate levels are an accurate indicator of true long-term exposure and that the variance in the NHANES population is similar to that of Ohira *et al*. (2008). In addition, they do not take into account other sources of variance like laboratory imprecision. Despite this, these estimates do provide some general idea of the likely magnitude of the bias due to the use of spot urine samples and provide at least some assurance that a factor of two is likely to cover the uncertainty associated with this database insufficiency.

With regards to intra-individual variability in serum T4 measurements, Andersen *et al*. (2001) examined this issue in 16 healthy men by collecting monthly measurements of serum T4 over a period of one year. They reported an individuality index (defined as $SD_{\text{analytical+intraindividual}} / SD_{\text{interindividual}}$) of 0.54. A ratio of the respective variances (i.e., R^2_x) would be about $(0.54)^2 = 0.29$. This possible 29 percent increase in the perchlorate-T4 regression coefficient is also within the two-fold uncertainty factor that was incorporated.

Relative source contribution

Recent food analyses have greatly expanded the data available on exposures to perchlorate in food, as described in the Exposure section of this document. Perchlorate has been detected in a wide variety of foods, including fruits, vegetables, grains, dairy milk, and human breast milk (Kirk *et al*. 2005, Pearce *et al*., 2007; Murray *et al*., 2008). Perchlorate levels in urine from NHANES, as reflected in the analysis of Blount *et al*. (2006), are generally supportive of the

FDA analysis. Together, these data demonstrate that food is the primary source of perchlorate for the general population.

At an ADD of 0.023 µg/kg-day and a range of average perchlorate exposure levels in food of about 0.09 to 0.39 µg/kg-day, the health-protective level is already exceeded by perchlorate from food. Mean exposures from food for women of childbearing age are about 0.1 µg/kg-day, according to the estimates of Murray *et al.* (2008). Thus it does not seem appropriate to allocate any specific fraction of total exposure to drinking water; all sources should be limited because the threshold of effect is already exceeded by the exposures derived from food. The concept of zero as a relative source contribution from water is unattainable. We have used 1 as a placeholder, indicating that no specific "acceptable" fraction can be calculated.

Drinking water at a PHG level of 0.6 ppb would provide about one/tenth the average exposure to perchlorate that would be obtained from food, for women of child-bearing age. One could say that this is equivalent to a relative source contribution of 0.1, which is below the guidelines of 0.2 to 0.8 recommended by U.S. EPA. However, these guidelines are intended for exposures that yield total daily doses below the effect threshold. In this case, since effects on thyroid hormone homeostasis are observed at common environmental exposures, the operating principle should merely be to decrease exposure to perchlorate as much as practical, and ensure adequate dietary iodine.

UPDATE TO "PERCHLORATE TOXICOLOGICAL PROFILE AND HEALTH ASSESSMENT"

In support of:
Perchlorate Maximum Contaminant Level (310 CMR 22.06)
Perchlorate Cleanup Standards (310 CMR 40.0000)

June, 2006

Office of Research and Standards
Massachusetts Department of Environmental Protection

Boston, Massachusetts USA

PREFACE

This document presents an update to MassDEP's 2004 *Draft Toxicological Profile and Health Assessment.* MassDEP postponed finalization of the 2004 document in order to consider the National Academy of Science's (NAS) report, *Health Implications of Perchlorate Ingestion,* which was released in January 2005, as well as additional information on perchlorate in breast milk that was not available to the NAS Committee. A separate MassDEP document, released concurrently with this document, titled *Addendum: Review of New Studies on Perchlorate*, addresses results from several even more recent scientific studies that were published during the internal review period for this updated document. This document reflects the scientific review and deliberation of MassDEP scientists, as well as distinguished members of the MADEP/DPH Advisory Committee on Health Effects. Two local members of the NAS committee met with MassDEP and its Advisory Committee to share information and perspectives on the health effects of perchlorate.

PEER REVIEW: DEP/MA DPH ADVISORY COMMITTEE ON HEALTH EFFECTS

MassDEP employed its standing advisory committee on health effects to advise it during the preparation of this document. The Committee membership was augmented with a number of specialists with expertise in the subject areas covered in our assessment of the health effects of perchlorate and standard setting. Participants included:

David Brown, ScD
Public Health Toxicologist
Northeast States for Coordinated Air Use Management
Boston, MA

Suzanne Condon, MPH
Assistant Commissioner
Bureau Of Environmental Health Assessment
Massachusetts Department of Public Health
Boston, MA

Gary Ginsberg, PhD
Toxicologist, Department of Public Health,
Division of Environmental Epidemiology
and Occupational Health
Hartford, CT

Dale Hattis, PhD
Toxicologist, Center for Environment and Technology
Clark University
Worcester, MA

David Kriebel, ScD.
Epidemiologist, Department of Work Environment,
University of Massachusetts
Lowell, MA

Philip Nasca, PhD
Epidemiologist, Professor and Associate Dean for Graduate Education
School of Public Health and Health Sciences
University of Massachusetts
Amherst, MA

Martha Steele, MPH
Chief Toxicologist, Bureau of Environmental Health Assessment
Massachusetts Department of Public Health
Boston, MA

Deborah C. Rice, PhD
Toxicologist, Environmental Health Unit
Maine Bureau of Health
Augusta, Maine

William Sweet, PhD
Toxicologist, Agency for Toxic Substances and Disease Registry
U. S. Center for Disease Control
Boston, MA

Robert T. Zoeller, PhD
Endocrinologist and Professor, Department of Biology
University of Massachusetts
Amherst, MA

ACKNOWLEDGEMENT

MassDEP is very appreciative of the participation of the members of the MassDEP/DPH Advisory Committee on Health Effects in the scientific peer review of MassDEP's draft updated toxicity assessment. Their generous commitment of time and tremendous expertise has been extremely helpful to our efforts on this important issue. The participation of independent public health scientists is a critical component of our state's efforts to protect public health and the environment in MA.

MassDEP also wishes to acknowledge two members of the National Academy of Sciences' Committee to Assess the Health Implications of Perchlorate Ingestion, Dr. Robert Utiger (Harvard University School of Medicine, Boston, MA) and Dr. Rosalind Brown (Children's Hospital, Boston, MA) for sharing information and perspectives on the toxicity of perchlorate with MassDEP and the Advisory Committee during the February 11, 2005 meeting. MassDEP is also grateful for the valuable input and information provided by Charles Emerson, MD, endocrinologist, University of Massachusetts Medical Center, Worcerster, MA.

EXECUTIVE SUMMARY

The following document provides an update of the Massachusetts Department of Environmental Protection's (MassDEP) 2004 *Draft Toxicological Profile and Health Assessment*, taking the National Academy of Sciences (NAS) report on perchlorate released in January 2005 into account, as well as other recent data.

Perchlorate inhibits iodide transport into the thyroid gland, which is hypothesized to be its primary mechanism of toxicity. The thyroid requires iodide to make thyroid hormones, which are essential for the normal growth and development of many systems in the body including the brain (MassDEP, 2004; U.S. Environmental Protection Agency, 2002a). Perchlorate is itself concentrated into breast milk in experimental animals and likely in humans as well; it may also be concentrated into thyroid cells, where it could impact other cellular functions. It may also interfere with iodide transport into breast milk, and interfere with a second iodide transporter found in the thyroid. Although not well understood, perchlorate also promotes the discharge of accumulated iodide from the thyroid gland at high doses. These effects of perchlorate, whether working in concert or independently, may, at sufficient doses, disrupt normal thyroid function and hormone dynamics, including altered synthesis of essential thyroid hormones (thyroxin (T4) and triiodothyronine (T3)).

Based on many lines of evidence premature infants and newborns are particularly at risk from perchlorate toxicity. Their sensitivity is attributable to the development of various organs, especially the brain, which occurs during fetal growth and early childhood. Appropriate levels of thyroid hormones are critical to these processes.

During the fetal and newborn periods the thyroid gland is also incompletely developed, increasing sensitivity to toxicants that disrupt the thyroid functions available. Pregnancy itself stresses maternal thyroid function increasing risks to the fetus. To further compound matters, breast milk is the sole source of the iodide a newborn needs to supply its capacity to synthesize thyroid hormones. Data suggests that maternal exposure to perchlorate may reduce iodide levels in breast milk, and thereby may increase neonatal sensitivity to perchlorate. This risk is further compounded by the fact that perchlorate is itself secreted, and may be concentrated, into the milk, presenting a double insult to the newborn's thyroid (Kirk et al. 2005).

Despite their likely sensitivity, there is essentially no good toxicity data on perchlorate exposures to pregnant women, the fetus and newborn. Thus, regulators must extrapolate from controlled studies on small numbers of healthy adults and/or data from animal (rodent) model systems. The current epidemiological data on larger groups of people exposed to perchlorate does not allow for safe exposure levels to be determined.

The MassDEP *Draft Toxicological Profile and Health Assessment* was undertaken as the result of a public request for guidance on drinking water perchlorate contamination, as no federal or state standards on this toxicant were available. In the MassDEP 2004 *Draft Toxicological Profile and Health Assessment*, MassDEP used a weight of the evidence approach in which data from animal and human studies were both assessed. These were found to yield overlapping toxicity values. Because the animal studies included exposures to the fetus and newborn, the

lifestages most at risk, Mass DEP relied on data from that research to derive an acceptable total human dose or RfD of 3×10^{-5} mg/kg-day.

While MassDEP was working on its 2004 Assessment the National Academy of Sciences (NAS) convened a scientific advisory committee to address perchlorate toxicity. The NAS completed its report in January 2005, and derived two possible RfD values using data from the 14-day perchlorate exposure study performed on small groups of healthy adults by Greer, et al. (2002). The majority of the NAS Committee members supported an RfD of 7×10^{-4} mg/kg-day, treating the lowest dose given to a group of 7 healthy adults in the Greer study as a no effect level and applying a total uncertainty factor of 10. One member of the NAS committee concluded that an additional uncertainty factor of 3, for a total uncertainty factor of 30, was needed to account for deficiencies in the database. Including this additional factor results in an RfD of 2.3×10^{-4} mg/kg-day.

The following document provides an update of MassDEP's *Draft Toxicological Profile and Health Assessment* taking the NAS report released in January 2005 into account, as well as even more recent data on perchlorate in breast milk and perchlorate in the U.S. food supply that was not available to the NAS Committee. In summary, MassDEP scientists in consultation with the MassDEP/DPH Advisory Committee on Health Effects concluded that a weight of the evidence approach should continue to be used to determine the most appropriate RfD value and corresponding drinking water limit. Thus, both the human and animal data were again considered. However, in part based on the NAS report, MassDEP is now placing more weight on the human data, which is used as the point of departure to derive MassDEP's current recommended RfD.

Upon consideration of the NAS report, MassDEP and the MassDEP/DPH Advisory Committee on Health Effects concurred with the NAS committee's view that the iodide uptake inhibition (IUI) data in the Greer et al. study constitute a reasonable basis for determining an RfD, provided that the inherent limitations and uncertainties in the data are appropriately accounted for. MassDEP believes the following factors must be addressed when using the Greer study to derive an RfD: protection of sensitive subgroups, since the Greer study involved adults; uncertainty in defining a true no adverse effect level, given the small number of subjects in the low dose group; and data gaps resulting from new information that became available after the NAS recommended an RfD.

Mass DEP is deriving an RfD for perchlorate by using the traditional approach and long-standing protocol also used for other chemicals. MassDEP supports the designation of iodide uptake inhibition (IUI) as a critical effect and point of departure (POD) for the development of an oral RfD for perchlorate. This position is consistent with U.S. EPA policy for setting RfDs (U.S. Environmental Protection Agency, 2002). The critical effect is defined as the first adverse effect, or its *known precursor*, that occurs to the most sensitive species, as the dose rate of the agent increases. We treat the lowest dose in the Greer study as a minimal Low Observed Adverse Effect Level (LOAEL), requiring application of an uncertainty factor of 3 to derive a No Observed Adverse Effect Level (NOAEL). MassDEP has concerns about the lowest dose in the Greer study being a no-effect level based on the facts that: due to the small number of subjects in the lowest dose group, there is low power to detect a statistically significant effect; averaging of

group responses obscures positive individual inhibition; a non-statistically significant IUI effect was observed at the lowest dose tested; and, good low dose corroborating data is lacking. Furthermore, we treat iodide uptake inhibition as an adverse effect, because to our knowledge, no human data exists that demonstrates the level of iodide uptake inhibition necessary to cause downstream effects, especially for the sensitive subgroups. At this time, the relationship between IUI and thyroid hormone synthesis, especially in the fetus and neonate, is unknown. Indeed the available data from studies on animals suggests that adverse effects may be associated with low levels of IUI. Thus, we treat IUI, which is an early event in the putative mechanistic pathway leading to perchlorate toxicity, as being causative of adverse effects and thus an effect to be avoided itself. Our use of this effect as a point of departure in deriving an RfD is consistent with US EPA policy for deriving RfDs.

MassDEP is also taking into account new information demonstrating perchlorate's widespread presence in breast milk in the US. Perchlorate was detected in 36 of 36 samples taken from a wide geographic area, at an average concentration of 10.5 µg/L and ranging up to 92 µg/L. These levels in breast milk substantially exceed recommended infant doses that can be derived based on the Mass DEP RfD *as well as* both those advanced by NAS.

The presence of perchlorate in breast milk and various foods, along with limited biomonitoring data collected by the U.S. Centers for Disease Control indicate that exposures to this compound are likely to be common. This data combined with the approximately 10-fold concentration of perchlorate from serum to milk that has been demonstrated to occur in animal bioassays raises significant concern about neonatal perchlorate exposure. Furthermore, based on a limited number of samples, the data suggest that perchlorate may also inhibit iodide transport into human breast milk. Because breast milk is the nursing infant's sole source of iodide and newborns are particularly sensitive to thyroid disruption due to their limited reserve capacity of thyroid hormones and developing thyroid function, reduced iodide levels in breast milk would increase neonatal sensitivity to perchlorate and other thyroid toxicants. Thus, perchlorate may present a double threat to nursing infants if their mothers are exposed, contributing to a reduced level of iodide available to the thyroid and inhibition of the thyroidal uptake of the iodide that is present. MassDEP has concluded that acceptable exposure levels for perchlorate should reflect the significant uncertainty and data gaps that exist relating to neonatal perchlorate exposures and toxicity attributable to nursing.

In part based on these data, MassDEP and the MassDEP/DPH Advisory Committee on Health Effects have concluded that an UF of 30, associated with the lower NAS RfD value, is the minimum that should be considered with this data. Taking the full range of uncertainties involved into account (e.g. including the short duration of the Greer study as well as several other uncertainties detailed in the following report) MassDEP has concluded that a total UF of 100 should be applied to account for variability in human sensitivity, uncertainty in the effect level and overall database deficiency[1]. Some members of the Mass DEP/DPH Advisory Committee on Health Effects indicated that an uncertainty factor of 300 could be supported and one suggested that 30 could be sufficient. Application of UF of 100 or 300 to the Greer data

[1] MA DEP's uncertainty factor choices are consistent with guidance from the US EPA (2002c), as well as from previous NAS committees who specifically evaluated the use of uncertainty factors in the development of drinking water guidance (National Research Council , 1980; National Research Council , 1986).

yields RfDs of 7 x 10^{-5} mg/kg-day and 2.3 x 10^{-5} mg/kg-day, respectively. A UF factor of 30 would yield an RfD of 2.3 x 10^{-4} mg/kg-day. MassDEP notes that, in recognition of the significant gaps in the toxicology database for perchlorate, the NAS report recommended that numerous additional studies be performed[2]. Data from these studies may ultimately help to reduce the current uncertainty on perchlorate exposure risks.

In summary, the human data can be interpreted, depending on how the fundamental uncertainties in the scientific data are addressed, to support RfDs of 2.3 x 10^{-4} mg/kg-day (based on the NAS lower value and also viewed as reasonable by one member of the MassDEP/DPH Advisory Committee on Health Effects); 7.0 x 10^{-5} mg/kg-day (MassDEP's recommended value, which all members of the MassDEP/DPH Advisory Committee on Health Effects supported) or 2.3 x 10^{-5} mg/kg-day (which some members of the MassDEP/DPH Advisory Committee on Health Effects indicated could be supported). RfDs derived from the animal data fall within a similar range (2.8 x 10^{-5} to 8.5 x 10^{-5} mg/kg-day, see main report). Based on the weight of the evidence MassDEP has concluded that an RfD value of 7.0 x 10^{-5} mg/kg-day, based on the Greer study data and a composite uncertainty factor of 100, provides a scientifically defensible basis for evaluating exposures. The MassDEP/DPH Advisory Committee on Health Effects unanimously concurred with this decision. The U.S. Environmental Protection Agency (US EPA) recently adopted the NAS higher RfD value (7.0 x 10^{-4} mg/kg-day), which is now included on the Integrated Risk Information System database. In part based on the new data on perchlorate in breast milk, MassDEP scientists and the MassDEP/DPH Advisory Committee on Health Effects unanimously concluded that this value did not fully account for the uncertainties surrounding science's understanding of perchlorate toxicity and exposures.

In the derivation of health based drinking water values, MassDEP considers the RfD, other sources of exposure, receptor body weight, and water ingestion rates. With respect to other sources of exposure, the available data indicates that perchlorate is frequently found in foods including many types of lettuce, store milk, fruits and other vegetables. To account for exposures to perchlorate from these foods, as well as data that indicates that perchlorate may be concentrated into breast milk, MassDEP is applying a 20% relative source contribution factor in its drinking water value derivation. This choice is consistent with how MassDEP has dealt with this issue in the derivation of drinking water guidelines and limits for other chemicals based on non-carcinogenic endpoints.

When the RfD values in the range noted above are translated into drinking water values, apportioning 20% of the acceptable dose to drinking water, the associated health based drinking water values are as follow:

Uncertainty Factor	RfD (mg/kg-day)	Drinking Water Limit (ppb)
10	7 x 10^{-4}	4.9
30	2.3 x 10^{-4}	1.6
100	7 x 10^{-5}	0.49
300	2.3 x 10^{-5}	0.16

[2] MA DEP and the Advisory Committee on Health Effects also noted that the NAS' extensive proposed research agenda serves to highlight fundamental uncertainties in the science on perchlorate toxicity and support a health-protective approach in deriving acceptable exposure limits to protect children's health.

The value of 0.49 µg/L is associated with MassDEP's recommended RfD[3]. The highest value, 4.9 µg/L, is derived from the NAS RfD, which is not supported by MassDEP or the MassDEP/DPH Advisory Committee on Health Effects. One member of the MassDEP/DPH Advisory Committee on Health Effects indicated that the NAS lower RfD alternative was reasonable. This RfD is associated with a drinking water value of 1.6 µg/L. Several members of the MADEP/DPH Advisory Committee on Health Effects suggested that a lower RfD could be derived, which would lead to a drinking water value of 0.16 µg/L, but viewed the MassDEP final RfD as appropriate.

In selecting final drinking water standards, Mass DEP considers the RfD, as well as additional factors. These additional factors include the frequency of contamination, analytical limitations, treatment options, costs, and for contaminants like perchlorate that may be introduced into drinking water as a result of treatments to address pathogens, comparative risks.[4]

In summary, MassDEP is recommending an RfD for perchlorate of 7.0×10^{-5} mg/kg-day, based on the Greer study data and a composite uncertainty factor of 100.

[3] Values for the bottle-fed infant, using infant exposure parameters, are 0.44 µg/L using the MA DEP RfD.
[4] MA DEP's previous drinking water advisory level of 1 ppb was based on the department's recommended RfD and a method reporting limit of 1 ppb, based on a modification of US EPA Method 314, which was then in effect. Improved analytical methods have now reduced detection limits to below 1 ppb.

1.0 INTRODUCTION

The Massachusetts Department of Environmental Protection's (MassDEP's) work on perchlorate began in 2002 when high levels of the chemical were detected in the groundwater on Cape Cod. Groundwater at the Massachusetts Military Reservation (MMR) contained perchlorate levels as high as 500 ppb, and 3 nearby public drinking water wells serving the town of Bourne were contaminated with levels in the low parts per billion range. Due to the fact that there were no federal or state standards for perchlorate, at the request of the Bourne Water District, MassDEP provided interim advice on drinking water, which stated that if levels of perchlorate exceed 1 ppb, that sensitive subpopulations should not consume the water. Sensitive subpopulations were defined as pregnant women, infants, children up to age 12 and individuals with hypothyroidism. MassDEP's Office of Research and Standards (ORS), a toxicology and risk assessment unit, based the interim guidance on the most current scientific studies that were presented in the U.S. Environmental Protection Agency's (US EPA) 2002 (2002a) draft health assessment for perchlorate.

In January 2003, MassDEP made a decision to set standards for perchlorate due to the need to clean up sources on Cape Cod and to protect the public health. Using established protocols, MassDEP ORS initiated an in-depth review of the scientific information on the toxicity of perchlorate towards establishing a reference dose (RfD), the starting point for setting standards to protect public health. The perchlorate standards that MassDEP intends to set are cleanup standards to support the state's hazardous waste site clean up program as well as a drinking water standard. As part of the regulation development effort, MassDEP has also collected test data on the occurrence of perchlorate in public water supplies in Massachusetts. The results indicate that approximately 1% of the public water systems contain perchlorate at levels greater than 1 ppb and as high as 1300 ppb.

As part of its RfD derivation process, MassDEP held three meetings of its MassDEP/DPH Advisory Committee on Health Effects, an external scientific peer review group, along with scientific representatives of the U.S. Department of Defense, on the toxicity of perchlorate. Information and comments received from these meetings were taken into account in the assessment and derivation of a draft RfD. In establishing the draft RfD, MassDEP utilized a weight of evidence approach where the available data on perchlorate toxicity was critically evaluated for consistency and biological plausibility in order to select an appropriate point of departure to derive an RfD for this compound that is appropriately health protective for all members of the population.

In its 2004 toxicity assessment, MassDEP noted that the concordance of effect levels observed for several endpoints, including iodide uptake inhibition, hormone effects and brain morphometry, as well as the consistency in observed effects with those that would be expected based on the proposed mode of action provides a strong basis for establishing an RfD. Mass DEP's assessment included consideration of both the human and animal data to ensure that the impacts of perchlorate on various life stages are taken into account. Whereas the human data (e.g. Greer et al., 2002) represents the effects of perchlorate on healthy adults (iodide uptake

inhibition) the available data is insufficient to directly address risks to sensitive groups. The animal data (e.g. Argus Research Laboratories, 2001) addresses the effect of perchlorate on the fetus and neonates who have limited thyroid hormone synthesis capacity. MassDEP's final draft document, "Perchlorate Toxicological Profile and Health Assessment" contained a recommended RfD of 3×10^{-5} mg/kg-day based on studies of the effects of perchlorate in animals (iodide uptake inhibition, alterations in hormone levels, and brain morphometry) and in humans (iodide uptake inhibition).

After MassDEP's effort to set perchlorate standards was well underway, US EPA's work on its draft health assessment for perchlorate was suspended and a federal level decision was made that the draft would be reviewed by a special committee under the National Academy of Sciences (NAS). The charge of the NAS Committee was to evaluate the scientific studies conducted on perchlorate and to assess the draft 2002 US EPA health assessment report.

In January 2005, NAS released its report, *Health Implications of Perchlorate Ingestion.* The report includes recommended RfD values, which was unexpected since this was not a task within the charge of the committee. The NAS Committee was not unanimous in its view of the RfD with the majority recommending an RfD value of 7×10^{-4} mg/kg-day. One dissenting member of the committee thought the RfD should be 3 times lower, or 2.3×10^{-4} mg/kg-day. The NAS recommended RfD values are approximately 7 and 20 times higher than MassDEP's 2004 recommended RfD.

To ensure that MA standards on perchlorate reflect current scientific data, MassDEP has reviewed the NAS report and recommendations as well as additional data on perchlorate including data on perchlorate in breast milk that was not available during the NAS review. Mass DEP's process for undertaking this review included a preliminary discussion with members of its external scientific advisory committee in late January 2005 and a meeting with members of the committee in mid-February 2005 to receive input and advice. Two NAS Committee members also attended the February meeting to share their perspectives on perchlorate with MassDEP and its Advisory Committee on Health Effects.

The following report updates MassDEP's draft perchlorate toxicological assessment and RfD derivation (MassDEP, 2004), based on MassDEP's consideration of the NAS's perspectives and views, new data on perchlorate in breast milk, recently published studies and feedback received from its external scientific review committee. In keeping with MassDEP's weight of the evidence approach to deriving an RfD for perchlorate, the report first addresses the use of the human data from the Greer study to derive an RfD, followed by further assessment of the animal data. A range of possible RfDs and potential drinking water values associated with these RfDs is derived based on other sources of exposure and dosimetry adjustments.

2.0 CALCULATION OF A REFERENCE DOSE FOR PERCHLORATE

2.1 HUMAN STUDY POINT OF DEPARTURE - GREER ET AL. (2002)

There are six primary human exposure studies involving perchlorate (Table 1). The study of Greer et al. (2002) is the most complete and has been chosen as the most suitable for development of a point of departure from the human studies. This was a 14-day exposure study involving a total of 37 healthy, euthyroid adult subjects. They were assigned to 4 perchlorate dose groups of 0.007, 0.02, 0.1, and 0.5 mg/kg-day perchlorate and given perchlorate daily in drinking water for 14 days. In 24 of the 37 subjects, 8- and 24-hour measurements of thyroidal ^{123}I uptake (RAIU) were made before exposure, on exposure days 2 and 14 and 15 days after exposure ceased. Both the day 2 and 8-hour measurements on post-exposure day 15 were omitted in another group of 13 subjects who were otherwise treated the same as the first group. Each group's pre-exposure baseline served as its own control. The results for the 24-hour RAIU measurements on day 14 of exposure have been chosen for further analysis and are presented in Figure 1. RAIU decreased relative to the baselines in the 3 highest doses. The low dose group had an 8 % decrease from the baseline mean, based upon only seven individuals. Greer et al.'s analysis determined that the small response seen in the low dose group was not statistically significantly different from the baseline for that group. Based upon this conclusion for the low dose, Greer et al. (2002) designated this dose of 0.007 mg/kg-day as a NOEL, a no observed effect level, even though they presented a more refined analysis which suggested that the true effect level was likely lower. This designation was subsequently seconded in an independent analysis of the Greer paper by the NAS peer review Committee (National Academy of Science, 2005).

MassDEP supports the designation of RAIU inhibition (iodide uptake inhibition or IUI) as a critical effect and point of departure (POD) for the development of an oral RfD for perchlorate. Our position is consistent with U.S. EPA policy for setting RfDs (U.S. Environmental Protection Agency, 2002). The critical effect is defined as the first adverse effect, or its *known precursor*, that occurs to the most sensitive species, as the dose rate of the agent increases. RfDs have been set based on precursor biochemical changes such as plasma or red cell cholinesterase inhibition for various organophosphates such chlorpyrifos and malathion and induction of liver enzymes such as for 1,4-dibromobenzene and other chemicals (U.S. Environmental Protection Agency, 2005).

While it has been argued that IUI is not an adverse effect (National Academy of Science, 2005) in adults, but rather a precursor to adverse effects, it most certainly would seem to have the potential to causally lead to adverse effects in some circumstances. In its report, NAS stated that iodide uptake would need to be inhibited to a level of 75% or more for extended periods in healthy adults in order to cause truly adverse effects. No experimental data or quantitative assessment was provided in support of this statement. To our knowledge no human data exists that demonstrates the level of iodide uptake inhibition necessary to cause downstream effects, especially for the sensitive subgroups. At this time the relationship between IUI and thyroid hormone synthesis, especially in the fetus and neonate, is unknown. No pharmacodynamic model is available to address this issue. In fact, physiologically-based pharmacokinetic (PBPK) modeling combined with experimental data suggests that, in rodents, iodide uptake inhibition of

less than 2% may be associated with adverse effects on thyroid hormone status and, possibly, neurodevelopmental endpoints. Thus, there are no objective data addressing the degree of IUI that would lead to adverse downstream effects. Furthermore it is likely that this level would be variable. Clearly IUI is an element of perchlorate's mechanism of toxicity and not merely indirectly associated with its adverse effects. It may thus predispose individuals to sensitivity to other thyroid toxicants or conditions that impact iodide status, could lead to transient, but physiologically significant, changes in downstream parameters and/or could lead to adaptive responses that themselves may have impacts not yet understood. MassDEP believes that it is prudent and appropriate to functionally treat IUI as an adverse effect in deriving a health protective RfD. Thus, for purposes of the remaining discussion in this report we will refer to this endpoint in the Greer study as a LOAEL. Because the effect observed in the Greer study is not a frank adverse effect it is treated as a minimal adverse effect in the assessment. This is consistent with established protocols for deriving RfDs. The MassDEP/DPH Committee on Health Effects concurred with this determination.

In addition to the issues described in the preceding paragraphs, we consider the Greer study as statistically weak for deriving an RfD and examine the strengths and weaknesses of two approaches for deriving a perchlorate RfD in the following discussion. The first method is the NOAEL/LOAEL[5] approach and the second the benchmark dose approach.

2.1.1 NOAEL/LOAEL Approach To RfD Derivation

2.1.1.1 *NOAEL/LOAEL Characterization*

MassDEP and its Advisory Committee on Health Effects note that the designation of the low dose of 0.007 mg/kg-day as a NOAEL has several weaknesses based upon: i. statistical considerations; ii. shortcomings of analysis of group-averaged data; iii. strength of supporting observations from other studies.

Statistical Considerations

Viewed from a statistical perspective, the Greer study had very low power to detect significant differences from the baseline levels of RAIU. Given the limited number of individuals in the low dose group (7) and the variability observed in measured RAIU about the mean baseline (18.1%) for the low dose group (standard deviation of 8.2), it is possible to determine the magnitude of change from the baseline mean that would be detectable within an acceptable level of error. Sample size calculation approaches presented in Green (1979) and Sokal and Rohlf (1995) can be used to determine the difference from the baseline mean that is detectable with a given error risk (alpha level). The minimum difference that could be discriminated from the baseline mean was ± 40% with a 1-in-20 chance of being wrong. This range is represented by the shaded box in Figure 1. Given the limitations of the Greer study, it was unable to reliably detect up to a 40% inhibition of iodine uptake. This interpretation is consistent with that of the U.S. Environmental Protection Agency (2002a) in its draft report on perchlorate. They concluded that a NOAEL could not be identified from this study and they designated the lowest dose as a

[5] NOAEL – no observed adverse effect level;; LOAEL – lowest observed adverse effect level.

LOAEL. Their peer review panel supported this conclusion (U.S. Environmental Protection Agency , 2002b).

Greer and coauthors themselves actually performed a more refined analysis to help identify what they called the true NOEL from this experiment using linear regression of RAIU against the logarithm of the doses. They extrapolated the derived equation to identify the dose associated with 0% inhibition of RAIU as in the range of 0.005 – 0.006 mg/kg-day. The authors note, however, that due to variability in the data, inhibition of RAIU of from 8.3-9.5% is possible at this dose. This interpretation presents what the authors call the true (or predicted) NOEL as less than the experimental NOEL. Given the slope of the dose-response (DR) curve, inhibition at 0.007 mg/kg-day could exist. The U.S. EPA in their response to comments on their draft perchlorate assessment offered the criticism of this approach that they saw no *a priori* reason to assume that the shape of the dose response curve was linear in the zone of extrapolation below the low dose group response values.

Group Averaging

The majority of the analyses of the Greer study results by others have focused on the dose-group averaged response values for purposes of deriving a NOAEL-based RfD. Greer presented individual subject response data in his Figure 2 (see Figure 2 in this report). A differential response to perchlorate exposure appears to exist which is a function of the baseline level of iodide uptake. Those 3 or 4 individuals (their figure is not entirely clear on this point) in the low dose group whose baseline RAIU was above about 15% exhibited a greater degree of inhibition of RAIU (approximately 18-26%) than those who had baseline uptakes below this level (7% inhibition to 40% increase). One possible interpretation of this result is that even in the healthy adult population, there is variation in iodide uptake efficiency with those having higher uptake efficiencies being more affected by perchlorate exposure-induced iodide uptake inhibition. Greer et al. do not present data on serum iodide concentrations, which would enable one to determine whether this differential response was a function of an individual's baseline serum iodide level. If such a relationship exists, then applying these results to the rest of the population would suggest that those who might be iodine deficient either through diet, life stage or as a result of their reproductive status might be more susceptible to perchlorate-induced harm. Included in this group of concern are pregnant women, their fetus and neonates.

In their statistically-based evaluation of the Greer data with the benchmark dose (BMD) approach the U.S. Environmental Protection Agency (2003) characterized the iodide uptake responses of two of the possibly three individuals whose uptake efficiency increased as a result of low dose perchlorate exposure as outliers. They noted that some dose groups were more highly variable in their responses to perchlorate exposure and that removing the responses of these two individuals improved the homogeneity of variances in the sample set across doses. An alternative view is that perhaps these "outliers" had low baseline iodide uptake efficiencies and were relatively insensitive to perchlorate exposure. The absolute changes in RAIU in these individuals with low baseline uptakes were not large (1-4%) so that perhaps what was being seen was statistical "noise" rather than aberrant responses. The effect of censoring them from the data set would be to drive the estimates of effect at the low dose towards higher response levels and

more closely support an interpretation that this dose was indeed a LOAEL, rather than a NOAEL.

Supporting Data

MassDEP thinks that the strength of the evidence cited to support Greer et al.'s (2002) results warrants critical appraisal. A consistent picture of the nature of perchlorate-induced inhibition in iodide uptake and responses of thyroid hormones from the five other human perchlorate exposure studies has been cited as support for the designation of the low dose of 0.007 mg/kg-day as a NOAEL and POD for the derivation of an oral RfD (National Academy of Science, 2005). One of the five studies is a repeat of one of the published studies with a longer, although unspecified duration and was reported through a personal communication (Brabant, 1994). Two others are short, non-peer reviewed publications (Lawrence et al., 2001; Braverman et al., 2004[6]). All three of these contained limited descriptions of the studies, data and statistical analyses. Interpretation of these results is difficult as the raw data for some have not been available and some data are not published. Information from such incomplete communications is not of the standard normally relied upon as a significant basis for setting regulatory standards.

The Lawrence et al. (2001) reference is a letter to the journal editor and the Braverman paper is the abstract for a poster presentation at a professional meeting. Only one of the studies (Braverman et al., 2004) contained an exposure at the same dose level as the Greer low dose. The level of detail reported in the abstract for that work and in the actual poster for the work was insufficient for determining whether or not the reported conclusions of no effect of perchlorate exposure on RAIU and thyroid hormone status were supported by the data. That study's low dose level is subject to the same criticisms listed for the Greer et al. (2002) study, in which small sample size limited its ability to discriminate experimentally-induced differences from the baseline RAIU. If the low dose results from the Greer et al. (2002) study and the Braverman et al. (2004) study were to be pooled, there would still only be a total of 12 (7+5) individuals from which inferences about perchlorate's low dose effects on iodide uptake and thyroid hormone status can be drawn. However, with no data on intersubject variance reported for Braverman's study and no data on RAIU inhibition at early time points post exposure, MassDEP does not view that study as sufficient supporting evidence for the designation of a NOAEL.

2.1.1.2 *Accounting for Uncertainty to Derive a Human Study*-Based *RfD*

Although a total uncertainty factor of 300 can be supported, MassDEP is recommending that a total uncertainty factor of 100 be applied to the lowest dose in the Greer et al. study (2002). Application of an uncertainty factor of 100 represents a change from MassDEP's 2004 toxicological assessment where a total uncertainty factor of 300 was applied. In determining how to apportion the total uncertainty factor of 100, MassDEP is assigning an uncertainty factor of **10 for variability in human sensitivity** (consistent with NAS) and a value of **3 for a LOAEL to NOAEL adjustment**. The remaining factor of **3 accounts for database deficiency**. An uncertainty factor of 3 for database deficiency is consistent with the view of the

[6] This study has now been peer-reviewed and published in J Clin Endocrin Metab (April 24, 2006); however, MassDEP's critique of the study (i.e., small sample size, low statistical power) still holds.

dissenting opinion of one member of the NAS Committee[7]. The bases for these designations are discussed below.

Interindividual Variability (Sensitive Individuals)

This uncertainty factor accounts for the variation in responses to exposure to a chemical in the population and for the possibility (given a lack of relevant data) that the database available is not representative of the dose/exposure-response relationship in the subgroups of the human population that are most sensitive to the health hazards of the chemical being assessed (U.S. Environmental Protection Agency, 2002c). The full human variability uncertainty factor of 10 is applied by the NAS to the Greer low dose and will be maintained by MassDEP.

This factor for human variability is intended to account for differences in inter-individual sensitivity across all life stages (neonates, children or adults). The human short-term study was conducted in a limited number of healthy volunteers who were iodine-sufficient. The study groups do not represent the sensitive subpopulations (pregnant woman, fetuses, children, hypothyroid individuals, and people with thyroid disease). Justification for the use of a 10 fold UF in the derivation of reference doses can be found in Krasovskij (1976) and Dourson and Stara (1983). More information to justify the use of this uncertainty factor for perchlorate can be found in MassDEP's toxicity report (MassDEP 2004).

The U.S. EPA in its guidance on deriving RfDs (U.S. Environmental Protection Agency, 2002c) provides the advice shown in Table 2 for evaluating evidence about susceptible subpopulations. Several of their criteria are germane to the knowledge base for perchlorate where greater weight should be reflected in the assignment of a higher UF when: the effect occurs at greater magnitude in one or more life stages, when different types of effects are seen in specific subpopulations, and when the effects differ in seriousness or degree of reversibility in specific subpopulations. For perchlorate, it is recognized that the pregnant mother, her fetus and the neonate are at particular risk from perchlorate-induced iodide deficiency. Since at these life stages, iodide deficiency may already exist in the absence of perchlorate exposure, added deficits as a result of perchlorate exposure could be beyond the compensatory capabilities of these individuals to withstand excursions in available serum iodide and concomitant changes in thyroid and pituitary hormones. The fact that we don't fully know the perchlorate dose-response relationship for this susceptible subgroup argues for conservativeness in the assignment of a UF.

The possible dependence of the perchlorate-associated IUI on the baseline level of iodide uptake seen in the individual responses from the Greer et al. (2002) study can also be viewed as either representing the variability across the human population, or alternately a unique subpopulation response.

[7] "One NAS committee member thought that the factor for database uncertainty should be greater than one and provided the following rationale: The RfD is derived from a study in which a group of only seven healthy adults was given 0.007 mg/kg of perchlorate daily for 14 days (Greer et al. 2002). Although two other studies had similar results, the total number of subjects is still small. In addition to the small number of subjects, no chronic exposure studies have been published. An uncertainty factor of 3 could account for the uncertainty surrounding the small number of subjects and the absence of a long-term study."

LOAEL to NOAEL Extrapolation

An uncertainty factor is normally employed in this category when the starting point for the derivation of an RfD is a LOAEL or LOEL in order to extrapolate the results based on effects observed at a low dose to the dose where no effect would be observed. MassDEP's view that the lowest dose in the Greer study (0.007 mg/kg-day) may not be a true no observed effect level has not changed. **MassDEP prefers to view this lowest dose as a minimal Lowest Observed Adverse Effect Level (LOAEL) and to maintain an uncertainty factor of 3**, for reasons developed in Section 2.1.1.1 (low study power to detect an effect, positive individual inhibition responses at the NOAEL obscured by group-averaging, and a lack of good low dose corroborating data) and as further described in MassDEP's 2004 draft toxicological assessment (MassDEP, 2004).

Derivations of RfDs take into account the nature of the critical effect, such as whether it is a biochemical change versus a frank adverse effect and whether the effect is on the causal pathway to more serious effects by way of an uncertainty factor. For example, when deriving an RfD that is based on a precursor effect, the uncertainty factor to extrapolate from a lowest observed adverse effect level to the no observed adverse effect level may be lower (e.g., three-fold) than if you were starting with frank effects such as brain damage (e.g., ten-fold).

When the responses of seven healthy individuals to perchlorate exposure are examined, it is apparent that even at low perchlorate doses, there are some individuals whose uptake of iodine can be substantially affected by perchlorate exposures. This observation calls into question the designation of 0.007 mg/kg-day as a NOAEL. An alternative analysis of the perchlorate dose response data from the Greer et al. (2002) study by the U.S. EPA (benchmark dose analysis) identified a BMDL dose of 0.002 mg/kg-d which suggests that biologically significant inhibition of iodine uptake can't be ruled out at a dose of 0.007 mg/kg-day (U.S. Environmental Protection Agency, 2003).

Database Insufficiency

This factor may be employed to adjust a NOAEL or LOAEL downwards to reflect the level of uncertainty in the database for the chemical. **MassDEP is recommending an uncertainty factor of 3 for database deficiency** due to concerns over:

(1) lack of chronic data. The duration of exposure in the Greer study was only 14 days, during which time iodide uptake inhibition of the thyroid was measured. Long-term effects due to iodide uptake inhibition, thyroid accumulation of perchlorate, thyroid hormone perturbation, or direct chronic effects of perchlorate in various other organs cannot be determined from this study. No oral chronic studies at this low dose level exist;
(2) emerging data indicating potentially widespread contamination of breast milk by perchlorate and related uncertainties regarding the degree to which perchlorate may interfere with iodide transport into breast milk, which could increase the sensitivity of the

neonate to perchlorate thyroid disruption, and data that indicates perchlorate may be concentrated into breast milk (see more detailed discussion in Sections 3.1 and 3.2)[8].

In addition, there is limited information on the interactive effects of perchlorate with other goitrogenic chemicals in the environment, such as nitrate.

Two other reviewers of the human perchlorate exposure literature (California Environmental Protection Agency, 2004; National Academy of Sciences, 2005) have concluded that, if the initial step of perchlorate-induced inhibition of thyroid uptake of iodide is limited, then the potential succeeding events that could lead to thyroid hormone changes and subsequent neurodevelopmental effects in offspring of mothers exposed to perchlorate or neonates directly exposed to perchlorate, will be prevented. This conclusion seems to reflect an assumption that pregnant women and the neonate, who in some cases may already be iodine deficient or have lower iodine reserves to supply hormone production needs during periods of perchlorate-induced iodine deficiency, will respond in the same way as healthy adults to perchlorate exposure. MassDEP has seen no data or argument that supports this assumption. There is a significant gap in our knowledge of how much IUI these susceptible subgroups can withstand and by extension, how they will respond to low-level perchlorate exposures.

2.1.2 Benchmark Dose Approach

Analysis of dose-response data with the benchmark dose approach has been coming into greater use in regulatory toxicology since its earlier introduction by authors such as Crump (1984) and Barnes and Dourson (1988). Setzer and Kimmel (Setzer et al., 2003) provide a more recent perspective on its use and note that it has the advantages over the NOAEL/LOAEL approach of using the entire set of data over all doses tested and as being more transparent and quantitative. It models the dose response curve in the range of observable data and then uses a model to predict the dose associated with a chosen level of response – the benchmark dose (BMD) (e.g., 5 or 10%). Confidence limits can be calculated and the lower confidence limit on the dose used as the BMD is called the BMDL. This BMDL value is used as the point of departure for calculation of an RfD. Unlike the NOAEL, especially as designated from the Greer et al. (2002) study, the BMDL accounts for the uncertainty in the estimate of the dose response that is due to the characteristics of the experimental design such as sample size.

[8] The detection of perchlorate in breast milk raises several issues. First of all, the degree to which it may interfere with iodide transport into the milk, which may *increase the sensitivity* of the neonate to the direct action of thyroid toxicants, including perchlorate, is a concern that has not been adequately addressed to date. The data suggesting that perchlorate may furthermore be concentrated into breast milk also raises a related but separate concern regarding *overall exposure levels to the neonate* (see Section 3.1 and 3.2). Neonate exposures to perchlorate in breast milk could ultimately be accounted for through the use of a quantitative adjustment to the maternal RfD to ensure that maternal to neonatal exposures do not exceed acceptable levels. However, sufficient data to do this is not currently available. Alternatively, an additional UF could be applied in the derivation of the maternal RfD and/or adjustments made to the proportion of the total maternal perchlorate exposure allowed from drinking water. As is discussed above and in section 3.1 and 3.2, MA DEP has concluded that the uncertainty regarding perchlorate's effect on iodide transport into milk provides partial support for the use of a database deficiency uncertainty factor. Uncertainty in perchlorate's concentration into breast milk supports the use of a conservative relative source apportionment factor to limit potential neonatal exposures from breast milk.

In cases where there are either problems or difficulties with the NOAEL/LOAEL approach for RfD derivation such as with perchlorate, the BMD advantages can be attractive. The challenge with using a BMD analysis on the Greer data is getting agreement on a POD for RAIU inhibition.

The U.S. EPA (U.S. Environmental Protection Agency, 2003) in its response to comments on its 2002 draft evaluation of perchlorate's effects and California (California Environmental Protection Agency , 2004) performed benchmark dose analyses on the Greer et al. (2002) data. US EPA censored two of the data points for the low dose group for statistical reasons and identified a BMDL 0.002 mg/kg-day for a 5% response rate. Irrespective of whether one calls a 5% response a no effect level or low effect level, the implication of this analysis is that the 0.007 mg/kg-day of the Greer et al. study is not a no effect level.

California's BMD analysis employed the U.S. EPA's BenchMark Dose analysis software, Ver. 1.3.1 and found the Hill model provided the best fit to the data, similar to EPA's conclusion. A BMDL of 0.0037 mg/kg-day was identified as a POD for the development of a RfD. This dose, like that identified by EPA with censoring, was below the NOAEL of 0.007 mg/kg-day identified by Greer et al. (2002) and NAS (2005) for this data set. It should be noted that the basis for the choice of a 5% response level in the modeling was to have a minimal biologically significant change as a point of departure.

The conclusion that MassDEP derives from these BMD analyses of the Greer et al. (2002) data is that a dose of 0.007 mg/kg-day cannot be confidently declared a no effect level for perchlorate exposure. This fact should be recognized either by designating the 0.007 mg/kg-day dose as a minimal LOAEL and assigning a partial amount (3) of the total UF (10) which could be assigned for extrapolating low effect data to a no effect level, or by employing a BMDL as the POD for assignment of uncertainty factors.

2.1.3 MassDEP Recommended Derivation of a Reference Dose Based Upon Human Data

The low dose of 0.007 mg/kg-day in the Greer et al. (2002) study is chosen as the point of departure for derivation of an RfD based upon human data. For a variety of reasons including poor statistical power of the study, the strong positive responses seen at this dose in some of the small study group and the weakness of potentially corroborating data for calling this a NOAEL, MassDEP views this dose as a minimal LOAEL.

The following uncertainty factors can be applied to adjust this dose downwards to an RfD such that it should be protective of all members of the human population:

10 - for sensitive individuals
3 - for minimal LOAEL to NOAEL extrapolation
3 - for database insufficiency.
100 TOTAL UF

$$\text{RfD} = \frac{0.007 \text{ mg/kg-day}}{100} = \mathbf{7 \times 10^{-5} \text{ mg/kg-day.}}$$

An alternative and supportable interpretation would be to apply a full factor of 10 for database insufficiency as has been recommended by some of our peer review committee members to produce a total UF of 300 and associated RfD of **2.3 x 10^{-5} mg/kg-day**:

10 - for sensitive individuals
3 - for minimal LOAEL to NOAEL extrapolation
10 - for database insufficiency
300 TOTAL UF

$$RfD = \frac{0.007 \text{ mg/kg-day}}{300} = \mathbf{2.3 \times 10^{-5} \text{ mg/kg-day}}$$

The lower of the two NAS RfDs, which relied on a total UF of 30 and which was supported by one member of the NAS Committee and one member of our Committee was **2.3x10^{-4} mg/kg-day.**

10 – for sensitive individuals
3 – for database uncertainty
30 TOTAL UF

$$RfD = \frac{0.007 \text{ mg/kg-day}}{30} = \mathbf{2.3x10^{-4} \text{ mg/kg-day.}}$$

2.2 USE OF ANIMAL STUDIES FOR SUPPORTING AN RfD BASED ON HUMAN DATA

2.2.1 Background

Information on the toxicity of perchlorate on the most sensitive subgroups of the human population is inadequate. Data on iodine deficient populations as well the mechanism of action believed to be responsible for perchlorate toxicity indicate that the most sensitive subgroups of the population for iodine deficiency are:

- pregnant women especially when marginally iodine-deficient or iodine-deficient,
- fetuses and infants of these women,
- premature infants,
- children, and
- hypothyroid individuals.

Due to a lack of adequate data on the toxicity of perchlorate in the sensitive subgroups, various rodent studies were conducted in the late 1990s and early 2000 to fill data gaps (U.S. Environmental Protection Agency , 1998a, 2002a). These studies are extensively discussed in the 2004 draft MassDEP perchlorate health assessment document (MassDEP 2004).

2.2.2 Justification for Use of Animal Data in the Weight of Evidence Assessment and RfD Designation Process

MassDEP is considering the rodent studies as supporting evidence in the perchlorate risk assessment process because: (1) the rat may be a good model to represent the most sensitive subgroups, especially the iodine deficient pregnant woman and the congenitally hypothyroid fetus which may depend only on maternal thyroid hormones during *in utero* development; (2) sensitive subgroups are being directly tested (the pregnant rat and its fetus and the neonate); and, (3) the observed results in the animals are consistent with the proposed mode of action of perchlorate, including the upstream effect of iodide uptake inhibition followed by downstream effects such as thyroid and pituitary hormone perturbations and thyroid and brain structural alterations. Appendix A contains further information on the justification for using the animal studies as supporting evidence in the derivation of an RfD for perchlorate.

2.2.3 Studies Conducted in Rats at Different Life Stages

The studies of perchlorate toxicity in animals demonstrated the following effects consistent with its proposed mode of action of perchlorate:

- inhibition of iodide uptake (Yu et al. 2000);
- decrease of serum T4 and T3 levels and increase of TSH levels (Caldwell et al. 1995; Springborn Laboratories, 1998; Argus Research Laboratories, 1998a,b, 2001);
- thyroid hypertrophy (increased cell size), hyperplasia (increased cell number) across life stages, and tumors[9] in F1 generation rats (rats exposed *in utero* and throughout lactation)[10] (Caldwell et al. 1995; Argus Research Laboratories, 1998a,b);
- alteration in brain morphometry (form and structure) and behavior in rat pups that were exposed *in utero* and after birth (Argus Research Laboratories,1998b, 2001; Bekkedal et al. 2000).

2.2.4 Critical Study (Argus Research Laboratories, 2001)

---

[9] It is suggested that thyroid cancer in humans resulting from perchlorate exposure is unlikely, since rats are sensitive to the development of thyroid tumors because their thyroid function is easily disrupted. Based on this argument, humans are much less susceptible than rats to disruption of thyroid function and, therefore, are not likely to develop thyroid tumors as a result of perchlorate exposure (NAS, 1995). The comparative sensitivity of humans and rats is discussed Appendix A. The database on long-term effects of perchlorate either on the sensitive population or the general population is insufficient to make such conclusions. A number of studies (Pendergast et al., 1960, Wahner et al., 1966; Williams et al., 1977; Williams, 1985; Levi et al., 1991; Pettersson et al., 1996; Vigneri et al., 1998) conducted in various parts of the world found that iodine deficiency may increase the incidence of thyroid malignancy and alter the type of cancer produced. Since perchlorate can contribute to functional iodine deficiency, its ability to cause thyroid cancer cannot be ruled out. Moreover, perchlorate was found to be a potent promoter of thyroid tumors in animals (Hiasa et al. 1987) and its effect in people with already initiated tumors is unknown. Based on its mode of action, perchlorate has the potential to contribute to thyroid tumors at doses sufficient enough to decrease thyroid hormone levels and change thyroid structure.

[10] Perchlorate was found to be nongenotoxic in various *in vitro* and *in vivo* studies, suggesting that the mechanism of tumor formation might be perturbation of the thyroid and pituitary hormone homeostasis (ManTech Environmental Technology , 1998; Zeiger, 1999).

Of the above listed studies, the critical study selected for perchlorate reference dose determination by MassDEP in 2004 and now in 2005 is the Argus (2001) neurodevelopmental study, which investigated sensitive endpoints at different life stages. In this study, perchlorate produced changes in pituitary and thyroid hormone levels and thyroid morphometry at different life stages. Brain mophometry changes were also reported, but these have been questioned due to experimental design and execution issues. The study is extensively discussed in the MassDEP (2004) document and is summarized below.

2.2.4.1 *Thyroid and Pituitary Hormone Alterations and Changes in Thyroid Structure*

Female Sprague-Dawley rats were treated with ammonium perchlorate at 0, 0.01, 0.1, 1.0, or 30 mg/kg-day in drinking water two weeks prior to cohabitation and continuing through the day of sacrifice. F1-generation pups were not directly dosed but might have been exposed *in utero* during gestation and via maternal milk and maternal water during the postpartum period. Significant changes were observed in thyroid and pituitary hormone levels at the lowest dose at different life stages (Table 3). Thyroid histopathology was also altered in both dams and pups, although at higher doses.

2.2.4.2. *Brain Morphometry Changes*

Because thyroid hormones are important for normal neurodevelopment, the Argus (Argus Research Laboratories , 2001) study also investigated treatment-related changes in brain morphometry. Significant changes, especially in the corpus callosum and striatum, were observed at the lowest dose. Similar changes in various brain regions, especially in the corpus callosum and striatum, were also observed in the Argus (Argus Research Laboratories, 1998a) study. These are summarized in Appendix B. However, various reviewers of the 2002 US EPA perchlorate toxicity document have challenged the brain morphometry data, especially the plane of cut of the corpus callosum, leading to considerable uncertainty in the quantitative interpretation of this data. . The NAS also reviewed several studies to establish biological plausibility of the effects of perchlorate on the corpus callosum, and concluded that although not widely recognized as a classic marker of neonatal hypothyroidism, increased thickness of the corpus callosum appears to be a biologically plausible effect. Based on the NAS report and further input from the MassDEP/DPH Advisory Committee on Health Effects, MassDEP has concluded that the brain morphometry data should not be quantitatively used in the derivation of an RfD. That data does however qualitatively support concern over perchlorate neurodevelopmental toxicity.

2.2.5 MassDEP Selected Animal Endpoint For Supporting RfD for Perchlorate

Changes in thyroid and pituitary serum hormone levels have been detected in several perchlorate treated species (Table 4) at different life stages, indicating that the hormone changes (Table 3) observed in the critical study (Argus Research Laboratories , 2001) are not isolated incidents. The NAS report also concurred that hormone changes were observed in the animal studies.

One issue with the hormone data is that the effects observed may be of too low a magnitude (Table 3, Table 5) to cause any further downstream effects (NAS, 2005). However, small and transient changes in thyroid hormone levels in pregnant women have been associated with

neuropsychological impairments (Haddow et al. 1999, Klein et al. 2001), and brain structural changes in rats (Auso et al. 2004). These studies are discussed in detail in Appendix C.

MassDEP views changes in thyroid hormone status as an adverse effect and has used these as the POD for deriving animal-based RfD values.

2.2.6 Summary and Conclusions

Perchlorate treatment in rats produces changes in thyroid hormone levels, thyroid morphometry and thyroid tumors consistent with its proposed mode of action. In the 2004 MassDEP draft perchlorate health assessment, MassDEP selected the Argus (2001) study as the primary basis for its draft recommended RfD for perchlorate. MassDEP utilized this study since it provided information on the direct effects of perchlorate on sensitive subgroups. MassDEP is continuing to use information from this study as part of its weight of the evidence approach but as supporting evidence for the human data rather than a primary point of departure for an RfD. MassDEP is making this revision in part based upon the National Academy of Sciences report (NAS, 2005).

Due to the controversy surrounding the brain morphometry data, MassDEP has concluded that the significant changes in thyroid and pituitary hormone levels are the preferable endpoint to use. The lowest observed adverse effect level (LOAEL) for this endpoint is 0.01 mg/kg-day, and this value is used as a point of departure to derive animal based RfDs for perchlorate (in support of the human data) as discussed below.

2.2.7 Derivation of RfD Values Based on the Animal Data

MassDEP has derived possible animal-data based RfD values using total uncertainty factors of 100 and 300, applied to the LOAEL dose in the Argus Laboratory study (2001). MassDEP and the MassDEP/DPH Advisory Committee on Health Effects concluded that an UF of at least 100 was needed to account for the uncertainties inherent in the use of the animal data with some participants supporting a UF of 300. Thus, both UFs have been used in the following calculations. Use of an uncertainty factor of 100 represents a change from MassDEP's 2004 toxicological assessment where a total uncertainty factor of 300 was applied.

For the total UF of 300 the apportionment is the same as presented in DEP's 2004 assessment. In summary, uncertainty factors included values of:

- 10, applied to adjust the LOAEL. This is the standard approach used when a NOAEL is not available. The size of the LOAEL-to NOAEL uncertainty factor may be altered, depending on the magnitude and the response at the LOAEL (U.S. Environmental Protection Agency, 2002c). In this case, a factor of 10 was deemed appropriate given that effects on multiple endpoints were observed including impacts on thyroid hormone levels.
- 10, to account for variations in susceptibility within the human population (intra-human variability) and the possibility (given a lack of relevant data) that the database available is not representative of the dose/exposure-response relationship in the subgroups of the

human population that are most sensitive to the health hazards of the chemical being assessed (U.S. Environmental Protection Agency, 2002c).
- 3, to account for interspecies extrapolation.

In the case of the total uncertainty factor of 100, MassDEP apportioned this as follows:

- an uncertainty factor of 10 for the LOAEL to NOAEL adjustment
- a composite value of 10 to account for variability in human sensitivity and interspecies extrapolation. This reduction in the UF for these factors is appropriate if the NAS contention that the rodent model is particularly sensitive to perchlorate-induced alterations in thyroid hormone status is correct.

As discussed in preceding sections the NAS position on this matter is, however, open to question, in which case a total UF of 300 would be justified.

Applying a total UF of either 300 or 100 to the study LOAEL results in RfD values of 2.8×10^{-5} mg/kg-day and 8.5×10^{-5} mg/kg-day, respectively. The derivation of these values is presented below:

For total UF of 300:

10 - for sensitive individuals
10 - for LOAEL to NOAEL extrapolation
3 - for interspecies extrapolation
300 TOTAL UF

$$\text{RfD} = \frac{0.0085 \text{ mg/kg-day}}{300} = \mathbf{2.8 \times 10^{-5} \text{ mg/kg-day}}$$

For Total UF of 100:

10 - LOAEL to NOAEL extrapolation
10 - composite UF for sensitive individuals and interspecies extrapolation
100 TOTAL UF

$$\text{RfD} = \frac{0.0085 \text{ mg/kg-day}}{100} = \mathbf{8.5 \times 10^{-5} \text{ mg/kg-day}}$$

3.0 ASSOCIATED DRINKING WATER VALUES

Drinking water values (or health based limits for contaminants in drinking water) are derived by converting a dose of the chemical in question to a concentration in water using exposure parameters and apportioning a fraction of the total reference dose (the RfD or total dose of the chemical in question allowed from all sources per day per kilogram body weight) to the drinking

water pathway. Typically, drinking water values are calculated using a standardized approach based on a 70 kg adult consuming 2 liters of water per day. In some cases adjustments may be made to account for differences in water intake rates and body weights of infants, children and pregnant women as compared to other adults. Although no current drinking water standard reflects the breast milk exposure pathway, MassDEP notes that further adjustment for exposures to nursing infants may also be warranted as they may experience quantitatively different exposures to chemicals, such as perchlorate, that are expressed in breast milk.

3.1 RELATIVE SOURCE APPORTIONMENT FACTOR

US EPA guidance recommends the use of a source apportionment factor in the range of 20% – 80% in the derivation of drinking water values for chemicals where exposures are likely to occur through additional pathways (U.S. Environmental Protection Agency, 1998a). A source apportionment factor is needed in the case of perchlorate because other exposures are likely.

Specifically, perchlorate has been found in common food items. In a preliminary study by the US Food and Drug Administration, 116 out of 128 samples of four types of lettuce from California, Arizona, New Jersey, and Florida contained perchlorate ranging in concentration from 1-129 ppb. Of 104 samples of cow's milk from across the country, 101 contained perchlorate with concentrations ranging from 3.1-11.3 ppb (U.S. Food and Drug Administration, 2004). In a separate study perchlorate was detected in all seven brands of dairy milk randomly purchased from grocery stores in Lubbock, Texas (Kirk et al. 2003). Most recently, perchlorate was detected in 46 out of 47 dairy milk samples from 11 states, with an average concentration of 2 ppb (Kirk et al. 2005). Another study focused on the development of analytical methods tested for perchlorate in a variety of food products, e.g., fresh fruits, vegetables, milk, alcoholic beverages, baby foods and other products harvested or processed in many parts of the world. The analysis showed the presence of perchlorate in most food products. Higher perchlorate levels were found in products from California (e.g., green grapes having 19 ppb), Mexico (e.g., 62.8 ppb in red tomato and 39.9 ppb in asparagus), and some South American countries, with cantaloupe from Guatemala having approximately 463 ppb of perchlorate. Foods produced in Canada and China showed the lowest level of perchlorate. Food products from Europe also showed relatively low perchlorate levels. The study also found that perchlorate can survive in food even after processing at a high temperature (El Aribi and Sakuma 2005). Although the data is limited, other food items are also likely to contain perchlorate. Recently, a Texas Tech investigator found perchlorate in samples of commercially grown wheat and alfalfa. In this study perchlorate concentrations ranged into the ppm range, considerably higher than those observed in the studies previously mentioned on lettuce and milk (Jackson et al. 2005). Although the database is limited for quantifying food and beverage perchlorate exposures, it does appear that perchlorate may be very pervasive in the U.S. food supply (U.S. and imported products). Concerns about exposures to perchlorate due to food ingestion are also supported by a recent study conducted by the U.S. Centers for Disease Control (CDC) on perchlorate in urine (Valentin-Blasini et al. 2005). CDC analyzed urine samples collected anonymously from healthy adult donors from Atlanta, Georgia, an area with no known perchlorate drinking water contamination. The limited sampling event of only 61 samples produced results showing that perchlorate was detectable in all of the urine samples ranging from 1 to 35 μg of perchlorate/g of creatinine.

The available human data also indicate that neonatal exposures to perchlorate in breast milk are likely to be widespread. Perchlorate has been detected in the breast milk of subjects from the Chilean cities of Chantaral at 19 µg/L (ppb) (where the water concentration was 5-7 µg/L (ppb)) and in Taltal at 104 µg/L (ppb) (where the water concentration was 100-120 µg/L (ppb)). Data also demonstrates that perchlorate is also common in breast milk in the US. In the study noted above, breast milk samples from all 36 individuals tested contained perchlorate. The maximum concentration was 92 µg/L with an average concentration of 10.5 µg/L (Kirk et al, 2005). The individuals tested were from 18 states indicating that perchlorate contamination of breast milk is likely to be widespread. These data indicate that breast-fed neonates may experience significant perchlorate exposures from breast milk. Neonatal consumption of breast milk with the average concentration of perchlorate reported in the Kirk et al study would result in exposures that exceed both the RfD values recommended by the NAS, as well as that recommended by Mass DEP.

Thus, the available data clearly demonstrates that perchlorate is prevalent in common foods and suggests that exposures to perchlorate from such consumables may be substantial. In addition, other dietary and environmental thyroid toxicants acting through a similar mechanism (e.g. nitrate) exist and will contribute to overall levels of thyroid disruption. Mechanistically, exposures to all such agents should be considered. Unfortunately the data is insufficient at this time to derive population-based exposure distributions from consumption of other perchlorate containing food items or to evaluate aggregate exposures to other thyroid toxicants.

In situations where other exposures are likely but the data is insufficient to quantitatively evaluate the relative contributions of other sources, federal and state drinking water programs often use a 20% source apportionment factor in drinking water limit derivations. In such situations, MassDEP has consistently used 20% in all of its drinking water guidelines based on non-cancer endpoints. Given the available data, MassDEP has concluded that a 20% factor is appropriate in the case of perchlorate.

3.2 ADJUSTMENTS FOR NEONATAL EXPOSURE

MassDEP scientists and members of the MassDEP/DPH Advisory Committee on Health Effects have noted that perchlorate risks to neonates are of particular concern due to their limited reserve capacity of thyroid hormones, incompletely developed thyroid functions, and higher liquid consumption rate per unit of body weight (of water in formula and/or breast milk). Although a concern, MassDEP did not focus on the issue of neonatal dosimetry in its earlier 2004 Draft Assessment because the proposed drinking water limit guideline of 1 ppb was determined by analytical limitations. Adjustment for neonatal dosimetry would have resulted in values below this limit, in which case the final guideline would still have defaulted to the analytical based reporting limit of 1 µg/L (ppb) in drinking water. In light of the higher RfDs proposed by the NAS and the data on perchlorate in breast milk, MassDEP has revisited this issue.

The US EPA in their 2002 draft assessment concluded that dosimetric adjustment for neonates was not needed in the case of perchlorate because the available PBPK models indicated that infant internal doses would likely be less than those of adults at a given exposure. Thus, for

water at a given perchlorate concentration, although infants would be expected to consume a greater daily dose of perchlorate on a per kilogram body weight basis, other pharmacokinetic factors (such as protein binding levels; kidney clearance rates; volumes of distribution etc.) would be expected to reduce the resulting delivered dose and IUI in the infant compared to the adult. MassDEP, however, notes that the available PBPK data supporting this position are by no means definitive because the models have not to date been fully developed or verified with respect to the human fetus and neonate.

The pharmacokinetics of toxicants vary considerably across life stages and across species. Of particular relevance to this discussion is the fact that very significant changes in pharmacokinetic functions occur during fetal and neonatal development and these vary considerably between rodent and human neonates (Ginsberg et al. 2002). Although the NAS did not address the issue of neonatal dosimetry adjustment in their report (NAS, 2005), they also noted limitations of the PBPK modeling data, stating:

> "Although no formal sensitivity analysis was performed on the human PBPK model, it is likely that, in addition to the skin compartment, urinary clearance of both [*sic*. perchlorate and iodide] and the plasma-protein binding of perchlorate may be important for additional future research. Furthermore, the PBPK model was developed for adult males and females (primarily healthy subjects although one subject with Graves disease was simulated) but not for pregnant or lactating females, human fetuses, neonates or children." (MassDEP note: the model under-predicted iodide uptake inhibition in the Graves disease patient modeled) and,
>
> "Given the important species differences in developmental biology and the current inability to validate extrapolation to human fetuses and neonates, such an approach (PBPK modeling) should be used with caution for these potentially sensitive populations."

The uncertainties in the PBPK models raise significant doubts regarding the use of the rodent neonate model outputs to conclude that human neonate internal doses will be less than in adults for a given intake. This is clearly an area where further research is needed. Given the available data MassDEP has concluded that it is appropriate to consider the default assumption of equal dosimetry in infants and adults (i.e., that the neonate will receive the same internal dose per unit of ingested dose as the adult) which necessitates adjustment of human infant exposures to account for their higher consumption of fluids per body weight compared to adults (and thus higher total ingested dose).

MassDEP notes that US EPA has previously included neonatal dosimetry adjustment in the derivation of a drinking water standard (for nitrate). To provide consistency, MassDEP has concluded that the body weight and liquid intake parameters used in the derivation of the US EPA nitrate limit are appropriate for dosimetric adjustment for perchlorate as well. Thus, an infant BW of 4 kg and consumption rate of 0.64 L/day were used to assess neonatal exposures.

These values are in the range of those reported in the 2002 interim US EPA Child Specific Exposure Factor Handbook (U.S. Environmental Protection Agency, 2002d)[11].

Formula-fed Infants. In the case of formula fed infants, a 100% apportionment to the drinking water used to make formula was selected. This is clearly appropriate, as exposures due to other foods are not a concern.

As noted in Table 6, possible drinking water values derived using these parameters are only marginally lower than those calculated using adult body weight and water consumption rates with a 20% source apportionment value.

Breast fed-Infants. The situation in the case of a breast fed infant is more complex as one must derive an acceptable drinking water value for the lactating mother that appropriately accounts for the potential concentration of perchlorate into breast milk. As noted earlier, perchlorate is expressed into breast milk and may also inhibit iodide transfer into the milk[12]. Furthermore, animal data indicate that perchlorate may be *concentrated* into breast milk[13]. Breast feeding infant exposures to perchlorate will therefore reflect the total maternal perchlorate exposure and the degree to which it is concentrated into breast milk and may well, on both an absolute and an adjusted body weight basis, exceed the exposures experienced by adults consuming contaminated water. Therefore, to account for the potential concentration of perchlorate into breast milk and ensure that breast milk concentrations do not exceed levels acceptable for the neonate, total maternal exposures may need to be well below RfDs for adults.

With respect to neonatal exposures, an acceptable breast milk perchlorate concentration can be derived for any selected RfD value. For example, based on a 4 kg infant consuming 0.64 L of breast milk and using the lower of the two NAS RfDs (2.3×10^{-4} mg/kg-day, which is the highest RfD that MassDEP and its MassDEP/DPH Advisory Committee on Health Effects believe can be supported), the breast milk concentration of perchlorate would need to remain below 1.4 µg/L (ppb) to keep infant exposures below the RfD. Based on MassDEP's recommended RfD of 7×10^{-5} mg/kg-day, the breast milk value would be 0.42 µg/L (ppb). Based on the average breast milk concentration from the US samples of 10.5 µg/L, a 4 kg newborn consuming 0.64 L of milk per day would receive a dose of 1.68×10^{-3} mg/kg-day, exceeding the MassDEP RfD and both of the NAS RfD values (2.3×10^{-4} mg/kg-day and 7×10^{-4} mg/kg-day).

---

[11] The 2002 interim US EPA Child Specific Exposure Factor Handbook (U.S. Environmental Protection Agency, 2002d) recommends a breast milk consumption rate of 0.74 L/day for 1-6 month old infants. The mean value for 1-month old infants was reported to equal 0.70 L/day. This reference presents smoothed 50th percentile body weights for one-month old male and female infants as 4.29 and 3.98 kg, respectively.

[12] Based on a *very limited* number of samples from this study population, for breast milk samples with a perchlorate content greater than 10 µg/L, the iodide content of the breast milk (the nursing infants sole source of iodide) was reported to be inversely proportional to the perchlorate concentration (r^2 of >0.9; $n = 6$) (Kirk et al. 2005). Thus, nursing infants may be subjected to a "double insult" if their mothers are exposed to sufficient perchlorate; a reduced level of iodide available to the thyroid and inhibition of thyroidal iodide uptake by perchlorate.

[13] The perchlorate concentration in the milk of lactating rats exposed to a perchlorate dose of 0.01 mg/kg-day was close to 10-fold higher than the concentration in the maternal serum (Clewell et al. 2003, Fig 2 panels A and E). In this case the PBPK model under predicted the observed breast milk concentrations.

Because of limited data on serum and breast milk perchlorate concentrations in people and the uncertainties with the PBPK models as they relate to fetal and neonatal life stages, as noted above[14], MassDEP has concluded that it is not possible at this time to derive meaningful quantitative estimates of infant perchlorate exposures from breast milk that would result from maternal drinking water exposures. However, the experimental data that indicates perchlorate is concentrated into milk from the serum suggests that, in order to keep the breast milk concentration of perchlorate below 1.4 µg/L, the perchlorate concentration in the drinking water of the nursing mother may need to be below this concentration[15].

Although, as noted throughout this discussion, there are significant data gaps that preclude robust quantitative assessment of this exposure pathway, the qualitative data emphasize its potential significance relative to exposures and risks to those considered to be among the most sensitive to perchlorate toxicity. This argues for a conservative, health protective approach. As previously discussed, uncertainty regarding perchlorate's inhibition of iodide transport into milk, which could increase neonatal sensitivity to perchlorate thyroid effects, is one of several uncertainties that support MassDEP's use of a database deficiency uncertainty factor. The levels of perchlorate detected in breast milk also support the use of a conservative relative source apportionment factor for maternal drinking water exposures to perchlorate.

3.3 RfDS AND ASSOCIATED DRINKING WATER LIMITS.

In light of the issues discussed above, MassDEP scientists in consultation with the Advisory Committee on Heath Effects concluded that a weight of the evidence approach should continue to be used to determine the most appropriate RfD value and corresponding drinking water value. Thus, both the human and animal data were considered by MassDEP in its assessment. In part based on the NAS report, MassDEP is now placing more weight on the human data.

---

[14] At the 2/05 meeting of the MA DEP-DPH Advisory Committee on Health Effects, one participating NAS Committee member noted that premature infants constitute an additional group at risk. To our knowledge, PBPK models addressing perchlorate exposures to premature infants have not been developed.

[15] Note: Although the following calculations are very uncertain because of limited data, they support a health-protective approach to the selection of the uncertainty factors used to derive a final RfD and exposure apportionments used to derive any drinking water limit for perchlorate for lactating women. Serum perchlorate concentrations in individuals (9 men) exposed to approximately 0.14 mg/kg-day of perchlorate in drinking water averaged 0.61 mg/L (Lawrence et al. 2000). Based on this data and using a linear extrapolation, exposures to perchlorate at the NAS lower RfD of 2.3×10^{-4} mg/kg-day would be expected to result in a serum concentration of approximately 0.001 mg/L (note: the PBPK models suggest that proportionally higher serum concentrations may result at lower doses, so this value may be an underestimate of the serum concentration). Assuming that the 10-fold serum to breast milk concentration factor observed in rodents applies to humans as well, this would imply a breast milk perchlorate concentration of 10 µg/L. This value is 7-fold higher than the acceptable breast milk target concentration of 1.4 µg/L, which can be derived based on the lower of the two NAS RfDs, and 23 times higher than that which can be derived based on MA DEP's RfD. As the adult drinking water limit associated with the NAS lower value is 1.6 µg/L, the final drinking water limit for lactating women would, in this scenario, be well below 1 µg/L. The final drinking water limit for lactating mothers would have to be below 1 µg/L even on the basis of the higher NAS RfD, which is associated with an adult drinking water limit of 4.9 µg/L based on standard exposure parameters that do not account for breast milk. These preliminary calculations are by no means definitive but do suggest a need for further research to better delineate the relationship between maternal perchlorate exposures, levels in breast milk and exposures to the nursing infant.

MassDEP and its MassDEP/DPH Advisory Committee on Health Effects, noting that the statistical power of the Greer study was such that a 40% inhibition of iodide uptake would have had to occur to be statistically detectable with a reasonable level of confidence, have concluded that an UF of 30 is the minimum that should be used with this data. One Committee member supported this value over others. Based on the full range of uncertainties involved, including data which indicates that perchlorate may be concentrated into breast milk, the remaining members of the Advisory Committee on Health Effects recommended that a total UF of at least 100 should be applied. Some members indicated that a higher UF of 300 could be supported. Application of UFs of 100 or 300 to the Greer data yields RfDs of 7×10^{-5} mg/kg-day and 2.3×10^{-5} mg/kg-day, respectively. As discussed in preceding sections, the animal data can support RfDs of 2.8×10^{-5} and 8.5×10^{-5} mg/kg-day. These values are in the same range as those that can be derived from the human data.

These RfD's along with the associated drinking water values are summarized in Table 6. The higher of the two NAS RfDs is footnoted in the Table for comparative purposes although MassDEP and the Advisory Committee on Health Effects unanimously concluded this value does not adequately account for the uncertainties in the data, including the breast milk exposure pathway[16].

Based on the weight of the evidence as discussed in this report, MassDEP has concluded that the RfD value of 7×10^{-5} mg/kg-day, based on the Greer study data and a composite uncertainty factor of 100, provides a scientifically defensible basis for evaluating exposures. This value is associated with a drinking water limit of 0.49 µg/L (adults) and 0.44 µg/L (formula-fed infants). Based on an RfD of 2.3×10^{-4} mg/kg-day, the highest value supported by the DEP/DPH Advisory Committee on Health Effects (one member) and the lowest value supported by the NAS Committee (one member) a drinking water value of 1.6 µg/L (adults) or 1.4 µg/L (formula-fed infants) would be supported.[17]

As noted earlier, upon completion of the above document and during the internal review period, a few new perchlorate studies and assessments were published and/or made available. For completeness, MassDEP reviewed these studies in light of their importance towards setting a perchlorate RfD and also received input from the MassDEP/DPH Advisory Committee on Health Effects. The results of this detailed review are presented in a separate Addendum along with conclusions that the newer studies do not present information sufficient to warrant altering MassDEP's proposed RfD value.

---

[16] To reiterate, breast milk exposure is an emerging issue that was not considered by NAS. Data released in February 2005, and thus not available to the NAS Committee, indicate that perchlorate is prevalent in breast milk at concentrations that frequently exceed values that would be appropriate for the neonate.

[17] MassDEP notes that if an adjustment is conducted using standard default values for the child body weight (10 kg) and child drinking water consumption (1 L/day), resulting drinking water limits are 0.046 ppb and 0.14 ppb based on total uncertainty factors of 300 and 100, respectively.

Table 6. Range of Possible RfDs and Associated Drinking Water Values Derived from Human and Animal Studies with MassDEP and NAS Assigned Uncertainty Factors

STUDY		Total Uncertainty Factor Applied			
		UF 300[1]	UF 100[2]	NAS UF 30[3]	Notes
Greer study	**RfD mg/kg-day**	2.3×10^{-5}	7.0×10^{-5}	2.3×10^{-4}	-
	a) Health Based Adult Drinking Water Value (µg/L or ppb)	0.161	**0.490**	1.610	For 70 kg adult; 2 L/day water consumption; 20% source apportionment factor
	b) Formula-fed Infant Health Based Drinking Water Value	0.137	**0.438**	1.373	For 4 kg infant; 0.64 L/day formula consumption; 100% source apportionment factor
Argus study	**RfD mg/kg-day**	2.8×10^{-5}	8.5×10^{-5}	NA	-
	a) Health Based Adult Drinking Water Value (µg/L or ppb)	0.196	0.595	NA	For 70 kg adult; 2 L/day water consumption; 20% source apportionment factor
	b) Formula-fed Infant Health Based Drinking Water Value	0.167	0.507	NA	For 4 kg infant; 0.64 L/day formula consumption; 100% source apportionment factor

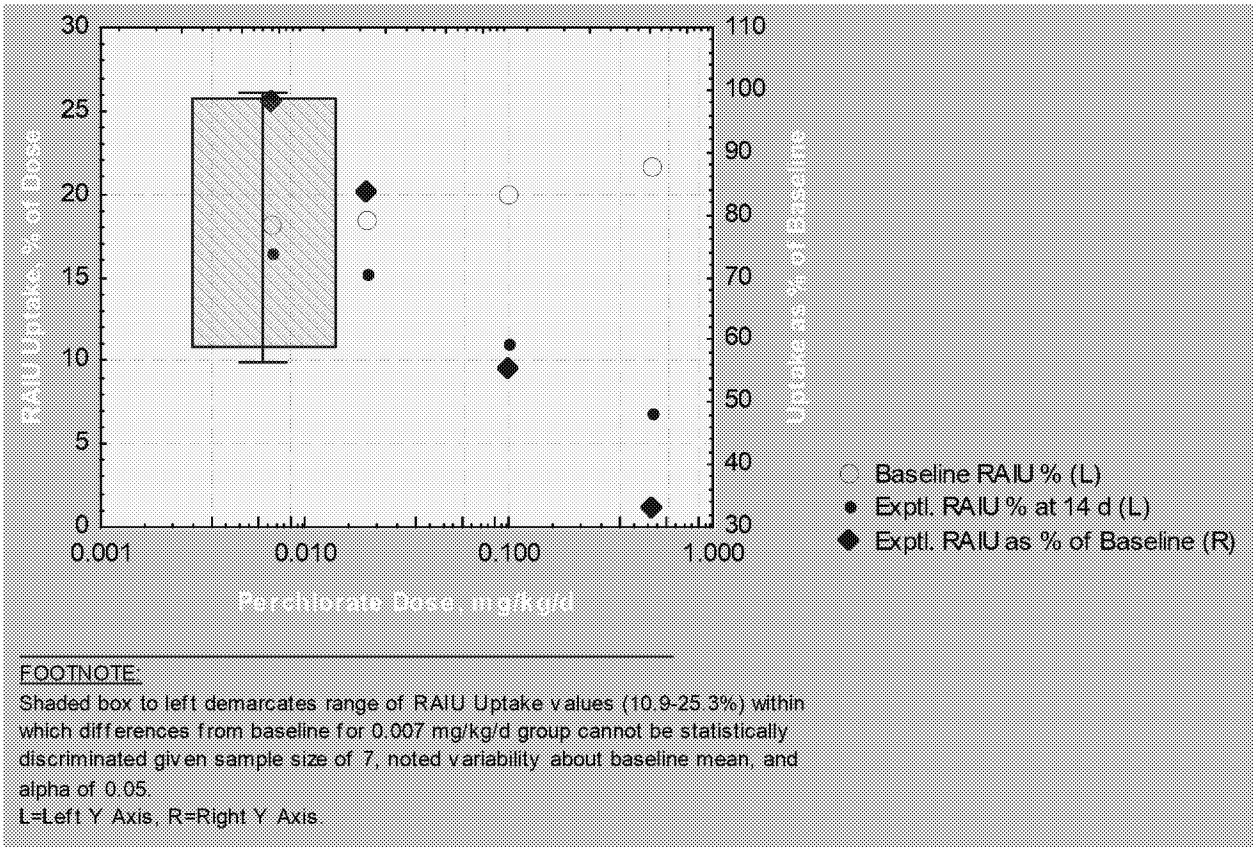
Table notes:

1 RfD value that would result from use of an UF of 300, an option that some members of the MADEP/DPH Advisory Committee on Health Effects indicated could be supported by the data.

2 Final MassDEP proposed RfD value, unamimously supported by MADEP/DPH Advisory Committee on Health Effects.

3 RfD value that one member of the DEP/DPH Advisory Committee on Health Effects and one member of the NAS Committee supported.

4 If the RfD, proposed by the NAS Committee (based on the Greer study) and adopted by USEPA were used, the associated drinking water limits for adults and infants would be approximately 4.8 µg/L and 4.2 µg/L, respectively.



FOOTNOTE:
Shaded box to left demarcates range of RAIU Uptake values (10.9-25.3%) within which differences from baseline for 0.007 mg/kg/d group cannot be statistically discriminated given sample size of 7, noted variability about baseline mean, and alpha of 0.05.
L=Left Y Axis, R=Right Y Axis.

APPENDICES

Appendix A

The Rat as an Animal Model for Perchlorate Toxicity

The NAS Committee stated that the rat is more sensitive than humans to perchlorate disruption of thyroid function and thus concluded that the rat was not a good model to study perchlorate toxicity. The NAS noted that rats exhibit:

(a) higher thyroid hormone turnover rate and lower thyroid storage capacity than observed in humans;
(b) lower thyroid hormone levels in normal pregnant rats compared to normal pregnant women; and,
(c) delayed thyroid gland development in rat fetuses compared to human fetuses.

These issues are briefly discussed below:

Thyroid Hormone Turnover Rate and Thyroid Storage Capacity

Greer et al. (2002) pointed out that: (a) the rat thyroid is much more responsive to perturbation of iodine metabolism, leading to decreased hormone formation; (b) if thyroid hormone synthesis is prevented, the rat thyroid contains only enough hormone to last a few days, while the iodide sufficient healthy human thyroid has enough thyroid to last several months; and (c) the rat thyroid is rapidly upregulated in response to multiple treatments with perchlorate, a phenomenon not observed in humans treated for 14 days with perchlorate. These differences were also discussed by the National Academy of Sciences (2005). In the comparisons made between rats and humans above, it is not clear if the rat is expected to have thyroid hormone storage capacity and thyroid upregulation time frames exactly similarly to humans, or whether there are known human-equivalent time frames for these parameters that the rat failed to meet.

These conclusions on rat versus human sensitivity to perchlorate-induced thyroid function disruption seem to contrast with the general physiological literature on inter-species scaling. It is well known in physiology that physical dimensions, and physiological and biochemical functions in different species are functions of metabolic rate which in turn relates to various exponents of body weight (Kleiber, 1947; Adolph, 1949; Krasovskij, 1976[18]). This biological regularity provides a basis for the use of small animals as models for human toxicological and pharmacological studies and for interspecies extrapolation, provided appropriate adjustment is made.

[18] Intake of water, urine output, urea clearance, creatinine clearance, Diodrast clearance, hippurate clearance, oxygen consumption-basal, heartbeat duration, breath duration, ventilation, tidal volume, gut beat duration, total nitrogen output, endogenous nitrogen output, creatinine nitrogen output, sulfur output, oxygen consumption in liver slices, hemoglobin weight, myoglobin weight, cytochrome weight, nephron number, renal corpuscle diameter, and weight of heart, kidneys, lungs, liver, thyroid, adrenals, pituitary, stomach, intestine, and blood (Adolph , 1949); duration of pregnancy, number simultaneously born offspring, latent period of tumor formation, nerve and muscle cell dimension, maturation time of bone marrow, cellular elements, duration of erythrocyte life (Krasovskij, 1976).

Much of the fundamental work on this topic came from studies of metabolism in different sized organisms (Kleiber,1947). The work of others expanded to other physiological and morphometric variables relationships with size. Adolph (1949) reported over 30 mammalian biological parameters[17] to be mathematical functions of body weight. Adolph's work was verified by Krasovskij (1976). This author also established linear relationships among 100 mammalian biological parameters and body weight and described this relationship as "biological regularity". Krasovskij expressed this "biological regularity" by an allometric exponential equation of the form $x = ay^b$ or by a linear-line equation $\log x = \log a + b \log y$. When the biological parameter is standardized by dividing by body weight, the relationship becomes described by a negative exponential curve, or by a straight line with negative slope if both the biological variable and weight are log transformed. This weight standardization is the basis for the well- recognized rule that smaller organisms have higher metabolic rates per unit of body mass than larger organisms, whereas their absolute metabolic rates are of course less than those of much larger sized organisms. The generalized results from two classic interspecies sensitivity studies (Pinkel, 1958; Freidreich et al.,1966) found that smaller animals were less sensitive (i.e, require greater effective doses to produce the same effect than in humans) to chemical toxicity than larger ones when compared on a mg/kg body weight basis: an important point vis-à-vis perchlorate. Concomitantly, smaller animals like rats have greater weight-specific physiological parameter rates than humans.

These generalizations relate directly to thyroid functioning. Basal metabolic rate (BMR) was historically used as a clinical tool for determining thyroid status in humans. The production and secretion of thyroid hormone is related to body mass with the same exponent of 0.75 that holds for BMR (Hulbert et al., 2004). From this relationship, one can infer that the rates of these thyroid hormone processes are greater in rats (and likely other small animals) than in larger animals when expressed on a body weight basis. There does not, however, seem to be any significant relationship of either total or free thyroid hormone concentrations in the plasma of animals to weight (Hulbert et al., 2004). This finding for thyroid hormone production rate is entirely consistent with the classic metabolic-size and dose-size paradigm, yet it is a high turnover rate of thyroid hormones in rats that was cited by National Academy of Science (2005) as one reason for characterizing rats as being potentially more sensitive to perchlorate-induced disruption of thyroid function than humans. The existence of these two apparently contrasting views of thyroid function sensitivity in rats compared to humans suggests this issue deserves closer scrutiny and that it may be premature to dismiss rats as models for human perchlorate toxicity because of their greater responsiveness or sensitivity than humans. The situation that exists is what is expected based upon classic interspecies scaling relationships.

Thyroid and Pituitary Hormone Levels in Pregnant Women and Pregnant Rats

In humans, normal pregnancy is accompanied by a rise in serum levels of T4 and T3. However due to an increase in T4-binding globulin, the free T4 and T3 levels decrease during pregnancy (Glinoer et al., 1990). In contrast to findings in humans, serum T4 and T3 levels in the rat during 17 to 22 days of gestation are decreased, leading to reduced concentration of T4 and T3 in tissues, except for T3 in the brain (Calvo et al., 1990). If this late gestation phenomenon in the rat also occurs during other stages of pregnancy, the pregnant rat can serve as a good model to study the effects of perchlorate in marginally iodine sufficient and subclinically hypothyroid women

who would be expected to exhibit comparatively lower levels of thyroid hormones. Hollowell et al. (2002) estimated that 4.6 percent of the United States population has hypothyroidism (0.3 percent clinical and 4.3 percent subclinical). Kung et al. (2000) studied marginally iodine sufficient pregnant women and found that pregnancy in these women decreased T4 and T3 levels (Table 1), as was observed in pregnant rats by Calvo et al. (1990) and Versloot et al. (1994).

The usefulness of the rat as a model for pregnant women cannot be ruled out. Pregnancy itself puts pressure on the thyroid gland. Among other changes in thyroid function, pregnancy increases the demand for iodine due to pregnancy-associated iodide clearance by the kidney (because of increased glomerular filtration rate), and transfer of maternal iodide to the fetus (Glineor, 1990). Any decrease in iodide uptake inhibition caused by perchlorate could create a negative iodide balance at any stage in pregnancy, causing a decrease in thyroid hormone synthesis.

Delayed Rat Fetal Thyroid Gland Development

Much of the knowledge regarding the maturation of thyroid function in the fetus and neonate is derived from studies in rats. The rat is a good model to study human thyroid gland development and differs primarily in the timing of events. The thyroid gland of the rat fetus starts to function between days 17 and 18 of gestation (Morreale de Escobar et al., 1985). Because of this late development of the thyroid gland, the rat fetus depends entirely on the mother's thyroid hormone during the greater part of *in utero* development. The rat fetus may thus provide an animal model to study the congenitally hypothyroid human fetus. Congenital hypothyroidism is one of the commonest causes of mental retardation in humans and its causes and prevalence are presented in Table 2. Since the rat fetus has some contribution of its own thyroid hormone during the last stages of its *in utero* development, this fact should be taken into consideration when extrapolating data from the animals to humans. The human hypothyroid fetus may be more sensitive to perchlorate because of a lack of any other thyroid hormone sources except its mother's, throughout gestation.

In conclusion, data on perchlorate toxicity derived from studies on the rat should not be completely discounted. In fact, the rat may be a reasonable model to study the toxicity of perchlorate during sensitive human lifestages such as the pregnant woman and the congenitally hypothyroid fetus. MassDEP is therefore continuing to use the animal bioassay data in its analysis but as supporting information. In acknowledgement of the uncertainty about the sensitivity of the rat model in comparison to healthy adults, MassDEP has considered alternative uncertainty factor adjustments for the animal data.

Brain Morphometric Data from Animal Studies

The NAS (2005) document extensively discussed the Argus Research Laboratories (1998, 2001) brain morphometric analyses, and pointed out that there was no dose-effect relationship and no consistent effect across age and sex except for the corpus callosum which increased in size at the highest dose tested (10 mg/kg/day) at different life stages. The NAS also noted that the Argus (2001) study showed significant increase in the corpus callosum across life stages at all doses except the highest dose tested (30 mg/kg/day). The NAS was concerned about the lack of a dose-effect relationship after comparing the Argus (1998) and (2001) studies. In the Argus (1998) study the thickness of the corpus callosum was increased only at 10 mg/kg/day and not at 3 mg/kg/day. In contrast, the corpus callosum size was increased at doses ranging from 0.01 to 1 mg/kg/day, but not at 30 mg/kg/day in the Argus (2001) study.

However, the NAS did not consider the dosing protocols (duration of exposure and dose spacing) used in the two studies. In the Argus (1998) study, female rats were exposed to perchlorate beginning on gestation day 0, while in the Argus (2001) study, female rates were exposed 2 weeks before cohabitation with male rats. In the Argus (2001) study, female rats were made hypothyroid before pregnancy while the female rats in the Argus (1998) study, were euthyroid at pregnancy. Previous studies by Springborn Laboratories (1998) have shown that rats treated with perchlorate for two weeks had significant changes in thyroid and pituitary hormone levels at 0.01 mg/kg/day, which is the dose that resulted in changes in brain morphometry in the Argus (2001) study. These observations suggest that the two studies should only be qualitatively compared. Lack of dose-response concordance between the two studies should not be a valid reason to discredit the results of the studies.

The NAS (2005) document also discussed other issues surrounding the brain morphometry data including:

(a) method of brain tissue fixation and time since fixation before sectioning and slicing of tissues;
(b) variation in plane of section;
(c) differences in plane of sectioning across animals;
(d) coronal versus sagittal sectioning of the corpus callosum; and
(e) lack of non-blinded morphometric measurements.

The NAS report indicated that the Committee did not think issues (a) and (b) above were of concern in the overall evaluation of the brain morphometry data. Regarding issue (c), the NAS stated that the US EPA resectioned and reanalyzed brain tissues from PND 22 pups, which helped to dispel some of the concerns that have been raised about systematic differences in the plane of section among treatment groups. However, the NAS was concerned that the reanalysis of the brain tissues has contributed to the inconsistencies in the data set because the thickness of the striatum were decreased in the 2001 brain section and increased in the 2003 brain section from the same pups. Like the NAS, MassDEP also observed these inconsistencies while

reviewing the US EPA (2003) document in 2004. The data in the 2002 and 2003 EPA documents on the corpus callosum were consistent while the data on the striatum were inconsistent. MassDEP previously contacted US EPA scientists involved in the perchlorate toxicity assessment for clarification of the divergent results of the striatal data set. Dr. Geller (personal communication) explained that the 2002 analysis was based on the combined male and female data, while the 2003 analysis was based only on male data. As seen in Table 1, perchlorate dosing was associated with a decrease in striatal size in females and an increase in males. It is not clear why the male and female striatal data were combined for analysis when there is clear evidence of treatment and sex interaction.

Of note is the observation that the effects of perchlorate on the striatum are reproducible at multiple doses and multiple life-stages, as it is with the corpus callosum. Wahlsten (2002) also reproduced the results on the striatum. Moreover, the coronal sectioning of this region of the brain is said to be not as controversial as it is with the corpus callosum. Issues (d) and (e) are of concern, but these issues may not be sufficient grounds to discount the brain morphometry data.

While MassDEP is still concerned with some methodological problems of the brain morphometry data, the consistent observation of perchlorate-related effects in the corpus callosum and the striatum observed in two separate studies at different life stages, and the concordant morphometric measurements performed by two separate pathology laboratories cannot be ignored. The data suggest that perchlorate may change brain morphometry in rats exposed *in utero* and postnatally. Moreover, the NAS (2005) also stated that the corpus callosum thickness was increased at multiple doses and at several stages of development (PND10-12, PND22, PND 82-85) in two studies and is suggestive of a relationship between perchlorate exposure and altered neurodevelopment. The NAS also reviewed several studies to establish biological plausibility of the effects of perchlorate on the corpus callosum, and concluded that although not widely recognized as a classic marker of neonatal hypothyroidism, increased thickness of the corpus callosum appears to be a biologically plausible effect. Thus MassDEP views the brain morphometry data as qualitatively informative but is no longer relying on this data to quantitatively assess perchlorate risks.

Appendix C

Modest Thyroid Hormone Decrement in Pregnant Women and Impaired Neurodevelopment in the Offspring

Haddow et al.(1999) measured thyrotropin (TSH) levels in stored serum samples collected from 25,216 pregnant women (during the second trimester) in Maine between January 1987 and March 1990. They then located 47 women with serum thyrotropin concentrations at or above the 99.7th percentile of the values for all the pregnant women, and 15 women with values between the 98th and 99.6th percentile, inclusive, in combination with low serum T4 and free T4 levels. The 7-9 year old children of these women were further investigated, none with hypothyroidism at birth The authors then conducted 15 tests on the children of these women as well as controls, relating to intelligence, attention, language, reading ability, school attainments, and visual-motor performance. The staff giving the tests did not know whether the children's mothers were women with hypothyroidism or control women. To establish a suitable control group, the authors selected 124 children born to euthyroid mothers, matched for various items such as the women's age at delivery, gestational age at blood sampling, and duration of serum storage. A scoring system was used to check for possible differences in socioeconomic status of the families (number of years of education and occupation of both parents). They found that the children of the 62 women with high serum thyrotropin concentrations performed slightly less well on all 15 tests and scored, on average, 4 IQ points lower compared to controls. Of the 62 women with thyroid deficiency, 48 were not treated for hypothyroidism during pregnancy. The average IQ score of their children was 7 points lower than the controls. Haddow *et al.* (1999) concluded that that even mild and probably asymptomatic hypothyroidism in pregnant women could adversely affect the neuropsychological performance of their offspring. From the Haddow et al. study it can be seen that T4 decreases in the pregnant mother as low as 30% may be associated with neuropsychological deficits in offspring, which is in the range of the T4 decreases observed in the critical Argus Research Laboratories (2001) study (Table 1).

In a follow-up study, Klein et al. (2001) studied serum TSH concentrations of pregnant mothers at 17 weeks of gestation and performed the standard neuropsychological testing in the offspring at mean age of 8. These authors found that the severity of neuropsychological deficits in the offspring was associated with maternal hypothyroidism. The hormonal status of subjects in this study might not be different from those in the Haddow et al. (1999) study, as both studies appear to have used subjects from the same sample pool. The results of the Klein et al. study support a causal association of low thyroid hormone level in the pregnant woman and poor neuropsychological development in the progeny.

Modest and Transient Thyroid Hormone Decrement in Pregnant Rat and Altered Brain Structure in Offspring

Auso et al. (2004) designed an experiment where mild transient hypothyroidism was induced in pregnant rats by treating these rats with a known goitrogen (2-mercapto-1-methyl-imidazole) for

only 3 days, from gestation day 12 to gestation day 15. Maternal thyroid hormones transiently decreased by about 30% in this study, without clinical signs of hypothyroidism. The pups born to treated dams were tested for audiogenic seizure susceptibility 39 day after birth and killed after postnatal day 40 to examine brain structure. The structure and distribution of the cortex and hippocampus were altered in 83% of the pups. Pups born to the treated dams (52%) also responded to an acoustic stimulus, followed in some by seizures. The authors concluded that even mild hypothyroxinemia should be prevented before and during pregnancy. Such study designs could in the future help identify the threshold for thyroid hormone decreases associated with brain structure alterations and other thyroid hormone deficiency-related effects. Until then, the 11% (Table 1) decrease in T4 and the 35% increase in TSH observed in the Argus (2001) study should remain of concern. The dose of perchlorate (0.01 mg/kg/day) associated with these effects provides a reasonable point of departure for deriving an animal data based RfD for perchlorate.

DRAFT DELIVERABLE
Hi Eric,
For you review are the draft memos to accompany the perchlorate final action. Please let us know if you have question, concerns or need more information.
Thanks,
Lisa

Sam,

Eric has signed and initialed the transmittal memos. Note, the Action Memorandum still needs the OMB language stating the completion of its review.

Thanks,
Steph

Dave:
Attached for your review is the pass back document we prepared to respond to the OMB and the other federal agency comments received yesterday. The attached document (both in PDF and Word) reflect the changes we tentatively agreed to earlier today in our conversation with OMB staff.

Please advise if you are comfortable with our transmitting the attached document to OMB or if there are any further modifications you would like for us to make prior to sending. The perchlorate team and I will be ready to discuss any questions or comments you have at your earliest convenience.
Please note that we will be reviewing this mark-up concurrently with you to address any typographical errors that may have occurred while we were addressing OMB's comments.

Thanks for your continued support on this important action.

MEMORANDUM

SUBJECT: National Primary Drinking Water Regulations: Proposed Perchlorate Rule (Tier 1 Action; SAN 5555; RIN 2040-AF28) – **ACTION MEMORANDUM**

FROM: David P. Ross
Assistant Administrator (4101M)

THRU: Office of Policy (1803A)
Office of Executive Secretariat (1105A)

TO: Andrew J. Wheeler
Administrator (1101A)

PURPOSE

Attached for your signature is a proposed rule, titled "National Primary Drinking Water Regulations: Proposed Perchlorate Rule." We recommend signature and publication of this notice to solicit public comment on the EPA's proposal to establish a national primary drinking water regulation (NPDWR) and a non-enforceable maximum contaminant level goal (MCLG) for perchlorate under the Safe Drinking Water Act (SDWA). The proposed NPDWR includes an enforceable maximum contaminant level (MCL) of 0.056 mg/L (56 μg/L), which is proposed to be set at a level equal to the proposed MCLG. The EPA is seeking comment in the attached notice on whether the Agency should consider setting the perchlorate MCLG and MCL at alternative values of 0.018 mg/L (18 μg/L) and 0.090 mg/L (90 μg/L). The EPA is also seeking comment on whether it should withdraw the Agency's 2011 determination to regulate perchlorate in drinking water.

DEADINE/TIMELINE

In February 2011, the EPA published a final determination to regulate perchlorate in drinking water. Section 1412(b)(1)(A) of the SDWA requires that the EPA issue a proposed NPDWR within 24 months of the final regulatory determination and a final NPDWR within 18 months after the proposal. However, when the EPA consulted with the Science Advisory Board (SAB), the Agency received recommendations that the EPA prepare a pharmacokinetic model (i.e., a biologically based dose-response model [BBDR]) to predict the effects of perchlorate exposure on the thyroid function in pregnant women and their children, to develop the MCLG for perchlorate. The EPA collaborated with Food and Drug Administration scientists to perform the modeling recommended by the SAB and completed the analysis and associated peer reviews in March 2018.

In February 2016, the Natural Resources Defense Council (NRDC) filed a lawsuit for failure of the EPA to perform its mandatory duties of proposing and finalizing a regulation for perchlorate in accordance with timelines provided in the SDWA. The court-approved consent decree established deadlines for the EPA to sign a proposed rule by October 31, 2018, and a final rule by December 19, 2019.

The EPA was granted an extension on the consent decree for signature of the proposed rule until April 30, 2019. However, due to a partial government shutdown in early 2019, an additional extension was given for signature of the proposed rule until May 28, 2019. The EPA is addressing the consent decree requirements to sign a NPDWR and issue a MCLG for perchlorate in this proposed rule by May 28, 2019.

OVERVIEW

Perchlorate is an inorganic anion which occurs naturally. It is also manufactured as an oxidizer for rockets, missiles, and fireworks and can be an impurity in hypochlorite disinfectants. The public may be exposed to perchlorate through food and drinking water. When exposed, perchlorate interferes with the thyroid gland by inhibiting iodide uptake, which impacts the production of thyroid hormones that are crucial for normal growth and development. Poor iodide uptake in pregnant and lactating women is linked to delayed development and decreased learning capabilities in their infants.

The EPA proposes to establish a NPDWR and a MCLG and MCL of 0.056 micrograms per liter (mg/L) (56 ug/L) for perchlorate based on avoiding neurodevelopmental impacts in the most sensitive population, the children of pregnant women with low iodide intake. The standard is proposed at a level that will prevent these children from having intelligence quotient (IQ) decrements greater than 2 points and includes a margin of safety. The EPA proposes requirements for water systems to conduct monitoring and reporting on perchlorate, and to provide information on perchlorate levels to consumers. The EPA also proposes requirements for primacy agencies that implement the Public Water System Supervision program under the SDWA. The proposal includes a list of treatment technologies to enable water systems to comply with the MCL, including affordable technologies for small systems.

In the preamble to the proposed rule, the EPA presents the results of its economic analysis and the Agency's conclusion that the benefits of the proposed regulation do not justify the costs. The EPA seeks comment on whether the Agency should set the MCLG and MCL for perchlorate at alternative values of 0.018 mg/L (18 µg/L) and 0.090 mg/L (90 µg/L). These alternatives would avoid IQ decrements of 1 or 3 points, respectively, in the most sensitive population and include a margin of safety. Finally, the EPA seeks comment on whether it should withdraw the Agency's 2011 determination to regulate perchlorate in drinking water based on the new information that indicate perchlorate does not occur in public water systems with a frequency and at levels of public health concern. Under this alternative, the EPA would not issue a final MCLG or NPDWR for perchlorate.

The EPA has determined that the National Primary Drinking Water Regulations: Proposed Perchlorate Rule does not have disproportionately high and adverse human health or environmental effects on minority populations, low-income populations and/or indigenous

peoples, as specified in Executive Order 12898 (59 FR 7629, February 16, 1994), which establishes federal executive policy on environmental justice. This action would increase the level of environmental protection for all affected populations without having any disproportionately high and adverse human health or environmental effects on any population, including any minority or low-income population.

ANTICIPATED PUBLIC STAKEHOLDER RESPONSE

The EPA expects a variety of reactions and responses from stakeholders. Public health and environmental groups may state that proposed regulation is not sufficiently protective and that the EPA does not have the authority to withdraw a determination to regulate a contaminant under the SDWA. These groups may claim that the regulatory process, established in the 1996 SDWA amendments, is not functioning as intended because the EPA has not yet regulated a contaminant identified through the Contaminant Candidate List and Regulatory Determinations processes. Some stakeholders may be critical of the scientific analysis used to inform the derivation of the perchlorate MCLG and the estimate of benefits from the proposed regulation. Industry groups, including the American Water Works Association, the Perchlorate Study Group, the American Chemistry Council, and the U.S. Chamber of Commerce may state that the models have too much uncertainty and variability to be used to establish a drinking water standard.

INTERNAL DEVELOPMENT AND REVIEW PROCESS

The EPA workgroup consists of representatives from the Office of Water, the Office of Children's Health Protection, the Office of General Counsel, the Office of Policy, the Office of Research and Development, the Office of Land and Emergency Management, and the Office of Chemical Safety and Pollution Prevention. The Office of Water sought review and input of the draft *Federal Register* notice from this workgroup prior to submission for interagency review.

INTERAGENCY REVIEW

The Office of Management and Budget initiated review of the *Federal Register* notice: "National Primary Drinking Water Regulations: Proposed Perchlorate Rule" on April 15, 2019.

IMPACTS

The EPA estimates this proposed rule would impose an annual cost burden between $9.7 and $10.3 million. Approximately $3.1 to $3.2 million of that annual cost will be borne by states (and the Navajo Tribe) that have primacy to oversee implementation of the requirements. Between $6.6 and $7.1 million of the annual cost will be borne by public water systems and their rate payers. Monitoring and administration requirements are the majority of the annual cost. The EPA estimates that very few systems will have to install or operate treatment to comply with the regulation.

The EPA determined that the proposed regulation will result in annual costs that are less than one percent of revenue for small public water systems affected by this proposed rule. The average annual costs range from $88 to $94 for these systems. The EPA determined that the compliance costs for this action in any given year are less than the threshold set in the Unfunded Mandates Reform Act ($100 million in expenditures to state, local, and tribal governments in aggregate or to the private sector).

PEER REVIEW

The OW followed the EPA peer review policy with respect to the underlying scientific BBDR model used to derive an MCLG for perchlorate in this regulatory action. As stated above, the EPA sought recommendations from the SAB for developing the proposed MCLG.

To ensure that the EPA had implemented the SAB recommendations, the Agency convened an independent peer review panel to evaluate the BBDR models in 2017. The EPA considered all the recommendations from the 2017 peer review and implemented those needed to increase the scientific rigor of the model and modeling results.

The EPA convened a second, independent peer review panel in 2018 to evaluate the updates to the BBDR model. The EPA also presented several approaches to link the thyroid hormone changes in a pregnant mother predicted by the BBDR model to neurodevelopmental effects, using evidence from the epidemiological literature. The January 2018 peer review concluded that "the current models are fit for purpose to determine an MCLG."

RECOMMENDATION

I recommend that you sign the attached rulemaking, "National Primary Drinking Water regulations: Proposed Perchlorate Rule."

MEMORANDUM

SUBJECT: National Primary Drinking Water Regulations: Proposed Perchlorate Rule

FROM: Eric G. Burneson, Director
Standards and Risk Management Division
Office of Ground Water and Drinking Water

TO: Anita M. Thompkins, Acting Director
Office of Ground Water and Drinking Water

Attached for your approval and transmittal to the Office of Water for review is a *Federal Register* notice titled: National Primary Drinking Water Regulations: Proposed Perchlorate Rule.

The EPA is proposing to establish a maximum contaminant level goal (MCLG) of 0.056 mg/L and a national primary drinking water regulation for perchlorate, which includes an enforceable maximum contaminant level (MCL) of 0.056 mg/L, as authorized under the Safe Drinking Water Act (SDWA). The action includes proposed requirements for public water systems to conduct monitoring and reporting on perchlorate and to provide information on perchlorate levels to consumers. The proposal includes a list of treatment technologies to enable water systems to comply with the MCL, including affordable technologies for small systems. The EPA is also proposing requirements for primacy agencies that implement the Public Water System Supervision program under the SDWA.

The *Federal Register* notice presents the EPA's economic analysis of the proposed perchlorate regulation and the Agency's conclusion that benefits of the proposed regulation do not justify the costs. The proposal includes the EPA's request for comment on alternative MCL/MCLG values of 0.018 mg/L and 0.090 mg/L. Finally, the EPA seeks comment on whether the Agency should withdraw the 2011 determination to regulate perchlorate in drinking water based on the new information that indicate perchlorate does not occur in public water systems with a frequency and at levels of public health concern. Under this alternative, the EPA would not issue a final MCLG or NPDWR for perchlorate.

I recommend that you approve and transmit the attached notice to the Office of Water for review. If you need additional information or have questions pertaining to any aspect of this notice, please call me or have your staff contact Samuel Hernandez at 202-564-1735.

MEMORANDUM

SUBJECT: National Primary Drinking Water Regulations: Proposed Perchlorate Rule

FROM: Anita M. Thompkins, Acting Director
Office of Ground Water and Drinking Water

TO: David P. Ross
Assistant Administrator

Attached for your approval and transmittal to the Office of the Administrator is a *Federal Register* notice titled: National Primary Drinking Water Regulations: Proposed Perchlorate Rule.

The EPA is proposing to establish a maximum contaminant level goal (MCLG) of 0.056 mg/L and a national primary drinking water regulation for perchlorate, which includes an enforceable maximum contaminant level (MCL) of 0.056 mg/L, as authorized under the Safe Drinking Water Act (SDWA). The action includes proposed requirements for public water systems to conduct monitoring and reporting on perchlorate and to provide information on perchlorate levels to consumers. The proposal includes a list of treatment technologies to enable water systems to comply with the MCL, including affordable technologies for small systems. The EPA is also proposing requirements for primacy agencies that implement the Public Water System Supervision program under the SDWA.

The *Federal Register* notice presents the EPA's economic analysis of the proposed perchlorate regulation and the Agency's conclusion that benefits of the proposed regulation do not justify the costs. The proposal includes the EPA's request for comment on alternative MCL/MCLG values of 0.018 mg/L and 0.090 mg/L. Finally, the EPA seeks comment on whether the Agency should withdraw the 2011 determination to regulate perchlorate in drinking water based on the new information that indicate perchlorate does not occur in public water systems with a frequency and at levels of public health concern. Under this alternative, the EPA would not issue a final MCLG or NPDWR for perchlorate.

I recommend that you approve the proposed rule and sign the Action Memorandum, transmitting the attached notice to the Office of the Administrator for signature. If you need additional information or have questions pertaining to any aspect of this notice, please call me or have your staff contact Samuel Hernandez at 202-564-1735.

Hi Sandy,

Thank you for your edits. Your changes have been accepted and two typos corrected as follows:

DR to AW Memo:
Under Impacts: …and administration requirements consisted of the majority of the annual cost.

DR to BB Memo:
This action presents the results of the EPA's economic analysis of the proposed perchlorate regulation and the Agency's conclusion that benefits of the proposed regulation do not justify the costs.

Let me know if you have any questions.

Joe.

Importance: High

In this version, I also added the San and Rin in the subject line for the Transmittal memo.

Thanks for sending the Perchlorate package. I have a few edits/comments.

1. Thank you for preparing both a transmittal memo and draft action memo. Attached are comments and suggestions.

2. A minor edit regarding the NPRM file name and OMB's requirements. OMB is particular regarding the naming convention. I added the title to the first page of the FRN and changed the title of the Proposed Rule file to

   EO12866_SDWA NPDWR Perchlorate 2040-AF28 NPRM 20190305

3. I removed the first paragraph of the Tribal EO (see below) – which was the 1st paragraph in the old template. I did not change anything else in the body/text of the Tribal EO.

Executive Order 13175, entitled ''Consultation and Coordination with Indian Tribal Governments'' (65 FR 67249, November 9, 2000), requires the EPA to develop "an accountable process to ensure meaningful and timely input by Tribal officials in the development of regulatory policies that have Tribal implications." The definition of ''policies that have Tribal implications'' includes regulations that have "substantial direct effects on one or more Indian Tribes, on the relationship between the federal government and the Indian Tribes, or on the distribution of power and responsibilities between the federal government and Indian Tribes." Under Executive Order 13175, the EPA may not issue a regulation that has Tribal implications, that imposes substantial direct compliance costs, and that is not required by statute, unless the federal government provides the funds necessary to pay the direct compliance costs incurred by Tribal governments, or the EPA consults with Tribal officials early in the process of developing the proposed regulation and develops a Tribal summary impact statement.

Please send me the final versions of the memos and I'll print them.

Sandy

Scientists Back Use Of 2007 Risk Approach For EPA Perchlorate Standard

March 15, 2019
A team of scientists in an article accepted for publication in the journal *Regulatory Toxicology and Pharmacology* is backing the American Water Works Association's (AWWA) call for EPA to rely on a 2005 risk assessment in crafting a perchlorate drinking water standard that could spur a weaker limit than use of an alternative approach.
The recommendation from the team of five is at odds with findings from a peer review panel that in 2018 advocated for a modeling method that could justify a more-stringent perchlorate limit.
The article by the team of five says that while EPA's 2017 biologically-based dose-response (BBDR) model "represents a valuable research tool, the lack of supporting data for many of the model assumptions and parameters calls into question the fitness of the extended BBDR model to support quantitative analyses for regulatory decisions on perchlorate in drinking water."
It was written by Harvey H. Clewell, III, a principal consultant with the company Ramboll, and others including fellow consultants and Eric Hack, a research scientist with the company ScitoVation.
The team says that until more data can be developed to address uncertainties in the current BBDR model, EPA should continue to rely on the 0.7 microgram per kilogram bodyweight per day reference dose (RfD) the National Academy of Sciences recommended in 2007, the article says.
AWWA, which represents drinking water utilities, funded the analysis but was not involved in writing the article. The group has previously argued in favor of using the RfD in developing a future EPA perchlorate standard rather than alternative approaches.
EPA is under a judicial deadline of April 30 to propose a health-based maximum contaminant level goal (MCLG) and related enforceable drinking water standard for the rocket fuel ingredient perchlorate that takes into account technical feasibility and cost.
The article's findings differ from a contractor-run peer review panel that last year concluded in its final report, "Overall, the panel agreed that the EPA and its collaborators have prepared a highly innovative state-of-the-science set of quantitative tools to evaluate neurodevelopmental effects that could arise from drinking water exposure to perchlorate. While there is always room for improvement of the models, with limited additional work to address the committee's comments below, the current models are fit-for-purpose to determine an MCLG."
At a public meeting prior to the peer reviewers' report, one of the reviewers, Hugh Barton, reacted with surprise when AWWA Manager of Federal Relations Kevin Morley in public comments suggested that "the best available science goes back to the RfD . . . as most suitable for regulatory development."
After questioning Morley about the traditional calculation for a drinking water standard from an RfD, based on adult consumption and weight estimates, Barton said, "I'd be concerned that at a public drinking water [level of 24.5 parts per billion] that perchlorate would become the next Flint, Michigan."
Barton expanded on his concerns of using the RfD to form the basis for the MCLG at the end of the meeting, noting that EPA's proposed analysis in 2012 discussed various consumption rates and body weights for infants, children and/or pregnant women to set a standard protective of the most sensitive subpopulation -- the fetuses of women with hypothyroxinemia, or low iodine levels. Iodine is necessary for crucial neurodevelopment, and the fetus is dependent upon the mother for iodine.
Barton noted that EPA's 2012 analysis resulted in as much as a 10-fold difference in potential drinking water standards "because of the volume [of water consumed] per bodyweight." Of most concern to him, the analysis resulted in the same potential standard for pregnant and non-pregnant women, despite the difference in their iodine needs. "The simple calculation from the RfD that says they're the same is not particularly credible."
Authors' Findings

But Clewell and his co-authors say that while the hormone component of the BBDR model is "a scientific improvement in terms of incorporating the available biology, there is a lack of data to provide critical validation in multiple steps of the proposed approach and to support several assumptions/parameters within the BBDR model."

While no major structural defects in EPA's model were identified, there are uncertainties in the model parameterization that call into question its use for predicting very small changes in clinical hormone values, such as a 1 percent change in free tetraiodothyronine (fT4) that may result in an increase in the prevalence of hypothyroxinemia in pregnant women, the article says. Hypothyroxinemia is often associated with hypothyroidism, or low concentrations of fT4, despite increased concentrations of thyroid stimulating hormone.

While the model prediction for a 1 percent change in fT4 would yield a point of departure, or starting point for later analysis of the dose-response curve, lower than EPA's RfD, "that level of precision is a not supported by the comparison of the model predictions with available data," the article says. Comparing the point of departure from EPA's 2005 Integrated Risk Information System assessment of perchlorate with the points of departure calculated by the BBDR model shows the RfD "is protective for all of the endpoints from epidemiological studies and is consistent with a change in population fT4 levels of less than 5%."

The fundamental underpinning of the agency's risk assessment approach has been the use of an obligatory precursor as a conservative basis for protecting against downstream health effects, the article says.

But "[u]nless perchlorate concentrations in the blood are sufficient to disrupt iodine uptake, there is no plausible basis for suggesting an effect of perchlorate on thyroid hormone homeostasis or subsequent events leading to developmental or (in the rat) carcinogenic effects. The recent studies suggesting a relationship between perchlorate exposure and decreased fT4 do not impeach this causal relationship."

Therefore, until the significant uncertainties in the current BBDR model and draft MCLG approaches can be addressed, EPA should continue to rely on the RfD approach based on inhibition of thyroidal iodine uptake for any further regulatory action, the article says.

The EPA "RfD includes an intraspecies uncertainty factor of 10 'to protect the most sensitive population, the fetuses of pregnant women who might have hypothyroidism or iodide deficiency.' None of the predictions of the BBDR model suggest that this uncertainty factor is inadequate," the article says. -- *Lara Beaven* (lbeaven@iwpnews.com)

ABSTRACT

The United States Environmental Protection Agency's (USEPA) 2017 report, "Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water", proposes novel approaches for deriving a Maximum Contaminant Level Goal (MCLG) for perchlorate using a biologically-based dose-response (BBDR) model. The USEPA (2017) BBDR model extends previously peer-reviewed perchlorate models to describe the relationship between perchlorate exposure and thyroid hormone levels during early pregnancy. Our evaluation focuses on two key elements of the USEPA (2017) report: the plausibility of BBDR model revisions to describe control of thyroid hormone production in early pregnancy and the basis for linking BBDR model results to neurodevelopmental outcomes.. While the USEPA (2017) BBDR model represents a valuable research tool, the lack of supporting data for many of the model assumptions and parameters calls into question the fitness of the extended BBDR model to support quantitative analyses for regulatory decisions on perchlorate in drinking water. Until more data can be developed to address uncertainties in the current BBDR model, USEPA should continue to rely on the RfD recommended by the NAS (USEPA 2005) when considering further regulatory action.

Keywords: perchlorate, risk assessment, MCLG, BBDR model

INTRODUCTION

From a regulatory perspective, the critical effect of concern from exposure to perchlorate is disruption of thyroid function and the potential for thyroid-hormone-related effects on neurodevelopment in gestation; these effects represent downstream events resulting from competitive inhibition of iodide uptake by the perchlorate ion (USEPA 2002). Based on an analysis of the mode of action for perchlorate, the United States Environmental Protection Agency (USEPA) (2002) determined that inhibition of thyroid iodide uptake could be used as an obligatory precursor for these critical effects in a harmonized cancer/noncancer risk assessment for perchlorate (Figure 1). This mode-of-action directed risk assessment approach was used in the derivation of the current Reference Dose (RfD) for perchlorate of 0.0007 mg/kg/day (USEPA 2005). Following the recommendations of the National Academy of Sciences National Research Council (NRC) (2005), the point of departure (POD) for this RfD was a reported No Observed Effect Level (NOEL): a non-statistically significant mean of 1.8% (standard error of the mean 8.3%) decline in radioactive iodine uptake (RAIU) in healthy adults following two weeks exposure to a daily perchlorate dose of 0.007 mg/kg/day (Greer et al. 2002). An intraspecies uncertainty factor of 10 was applied to protect the most sensitive population, the fetuses of pregnant women who might have hypothyroidism or iodide deficiency.

Subsequently, the USEPA Office of Drinking Water (2008) published an Interim Health Advisory Level for perchlorate of 15 µg/L, based on the USEPA (2005) RfD of 0.7 µg/kg/day, as recommended by the NRC (2005). Determination of this Interim Health Advisory Level considered Physiologically-Based Pharmacokinetic (PBPK) Modeling (Clewell et al. 2007) to estimate the potential effect of perchlorate on iodide uptake in several sensitive subgroups, including the pregnant woman and fetus, the lactating woman and neonate, and the young child. Despite widespread scientific acceptance of iodide inhibition as an obligatory precursor to downstream toxicity endpoints, there was remaining concern regarding the level of protection for the population perceived to have the greatest susceptibility – the fetuses of hypothyroid mothers.

Over the next several years, the focus of research on perchlorate shifted to the development of a biologically based dose-response (BBDR) model of the hypothalamic-pituitary-thyroid (HPT) axis that could be linked with the PBPK model of perchlorate and iodide to predict dose-dependent interactions

of perchlorate with iodine hormone homeostasis as a function of iodide intake in an effort to more quantitatively account for the effects of low dietary iodide intake and hypothyroidism in pregnant women on fetal development (McLanahan et al. 2008, 2009; Fisher et al. 2012; Lumen and George 2017a, 2017b; Lumen et al. 2013, 2015).

The USEPA Science Advisory Board (SAB) (2013) report on perchlorate in drinking water supported the utility of BBDR modeling to help characterize the potential for neurological effects from perchlorate exposure:

> "As perchlorate research continues, studies in animals may provide important insights into the neurobehavioral consequences of perchlorate exposure. A physiologically-based pharmacokinetic/pharmacodynamic framework is well suited to help place these findings in the context of human perchlorate exposure."

The USEPA SAB (2013) identified a number of areas for improvement or modification of the existing models. However, they also noted that "Models can always be improved, but the goal is to have a model that is fit for the intended purpose.", apparently cautioning against perpetual model refinement at the expense of implementation, echoing the concern of the renowned statistician, George E.P. Box, who famously used to say: "All models are wrong but some are useful" (Box 1976).

Recently, the USEPA's Office of Ground Water and Drinking Water (USEPA 2017) responded to the Science Advisory Board recommendations and proposed novel approaches to inform the derivation of a Maximum Contaminant Level Goal (MCLG) for perchlorate, including the use of BBDR modeling in their report entitled "Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water". This MCLG approach (USEPA 2017) includes revisions to a previously developed and peer reviewed BBDR model (McLanahan et al. 2008, 2009; Fisher et al. 2012; Lumen and George 2017a, 2017b; Lumen et al. 2013, 2015) that was extended to predict the relationship between perchlorate exposure and thyroid hormone levels in sensitive life stages. These revisions aim to address suggestions by the USEPA SAB (2013), including the following:

- Derivation of a perchlorate MCLG that addresses sensitive life stages through PBPK/PD modeling;

- Expansion of the modeling approach to account for thyroid hormone perturbations and potential adverse neurodevelopmental outcomes from perchlorate exposure;
- Utilization of a mode of action framework for developing the MCLG that links the steps in the proposed mechanism leading from perchlorate exposure through iodide uptake inhibition to thyroid hormone changes and finally neurodevelopmental impacts; and
- Extension of "the [BBDR] model expeditiously to…provide a key tool for linking early events with subsequent events as reported in the scientific and clinical literature on iodide deficiency, changes in thyroid hormone levels, and their relationship to neurodevelopmental outcomes during sensitive early life stages" (USEPA SAB 2013, p. 19).

Model revisions presented in the USEPA (2017) report include: incorporating a description of the physiology of early pregnancy, biological feedback control of hormone production via thyroid-stimulating hormone (TSH) and human chorionic gonadotropin (hCG), and a description of the response to lower levels of iodide nutrition. In addition, an attempt was made to calibrate the model's behavior for upper and lower percentiles of the population, in addition to the population median, for thyroid hormone production. The report also included an uncertainty analysis for key BBDR model parameters.

For the development of the MCLG, USEPA (2017) proposed a two-stage approach linking the revised BBDR model results ("Stage 1") with quantitative information on neurodevelopmental outcomes from epidemiological studies ("Stage 2"). Stage 1 describes the thyroidal hormone levels in women of childbearing age with low to adequate iodide intake. In this stage, the revised BBDR model is applied to predict the relationship between perchlorate exposure and changes in thyroid hormone levels in early pregnancy. Data for Stage 2 of the approach is provided from epidemiological studies evaluating maternal thyroid hormone levels in early pregnancy and the relationship between changes in these levels and the observation of neurodevelopmental outcomes. The USEPA (2017) report also described development of a novel population-based approach that uses the revised BBDR model to estimate changes in levels of selected thyroid hormones, specifically free tetraiodothyronine (fT4) and TSH, resulting from perchlorate exposure that may result in an increase in the prevalence of hypothyroxinemia in pregnant women. Hypothyroxinemia (low circulating concentrations of fT4) is

111 often associated with hypothyroidism (low concentrations of fT4 despite increased concentrations of
112 TSH).

113 The evaluation and (potential) application of the perchlorate BBDR model will serve as an important
114 precedent for future consideration of such models by the agency, as it is only the second such model
115 to be seriously evaluated by USEPA and subjected to external peer-review. The first BBDR model to
116 be considered, formaldehyde nasal carcinogenicity developed by Conolly and colleagues (2003, 2004),
117 has been under consideration by the agency for more than a decade. Interest in the use of BBDR
118 modeling in risk assessment peaked in the 1990s when the draft USEPA (2003) Cancer Guidelines
119 identified these models as the preferred option for performing a cancer dose-response. However,
120 since that time, work in this area has waned, possibly due to the perceived difficulty of gaining
121 regulatory acceptance. By their nature, BBDR models are descriptions of complex biological systems
122 that necessarily include significant uncertainty. The challenge going forward will be to develop
123 approaches for characterizing that uncertainty in a risk assessment context and ensuring that these
124 complex models are fit for their intended purpose. It is with this consideration in mind that we have
125 performed a focused evaluation of the proposed USEPA (2017) approaches.

126 Our critical review focused on two key areas of importance for determining whether the current BBDR
127 model is fit for the purpose of supporting regulatory decisions based on predicted effect of perchlorate
128 exposure on human fetal development:

129 1. Evaluation of USEPA (2017) model revisions to the peer reviewed BBDR models, including
130 extending the model to early pregnancy, incorporating biological feedback control of hormone
131 production via thyroid stimulating hormone (TSH) and human chorionic gonadotropin (hCG)
132 signaling, calibration of the model for thyroid hormone effects, and uncertainty analysis for
133 key parameters. This evaluation included comparison of model output to results from key
134 human studies identified in previous assessments (Greer et al. 2002, Braverman et al. 2006,
135 Téllez et al. (2005a, 2005b), as well as in the USEPA (2017) document (Steinmaus et al.
136 2016);
137 2. Evaluation of USEPA (2017) approaches for linking BBDR results to neurodevelopmental
138 outcomes and identification of published literature to develop the quantitative relationship
139 between thyroid hormone levels and neurodevelopmental outcomes; and

After describing the results of this evaluation, we present a comparison of the results from the USEPA (2017) approach with results from previous USEPA assessments, in order to put the uncertainties in the BBDR approach in perspective against the potential impact of the new approach on the existing regulatory guidelines for perchlorate USEPA (2005, 2008).

METHODS

Evaluating Stage 1 of USEPA MCLG approach: Stage 1 of USEPA's MCLG approach relies upon the application of the BBDR model to predict the effect of perchlorate on the thyroid hormone in pregnant women at different iodine nutrition levels, with the goal of predicting fT4 hormone reduction in pregnant women with low dietary iodide. To evaluate the utility of the proposed model to support such predictions, we independently ran the model and tested model predictions against data from multiple studies. These exercises attempted to both duplicate BBDR model results for datasets that were used by USEPA (2017) to calibrate the model and to test the ability of the BBDR model to predict the well-described precursor event inhibition of iodide uptake, which was successfully described with previous versions of the perchlorate PBPK models (Merrill et al. 2003; Clewell et al. 2007). These simulations included:

- Steinmaus et al. 2016 – cross-sectional epidemiological study evaluation of serum and urine in pregnant women in California: used in USEPA (2017) to evaluate BBDR model predictions of perchlorate effects on fT4 and TSH
- Greer et al. 2002 – 14-day controlled perchlorate dose study in male and female adults in the US: used in USEPA (2017) to estimate urinary clearance parameters in BBDR model
- Braverman et al. 2006 – 6-month controlled perchlorate dose study in male and female adults: not used in USEPA (2017)
- Téllez Téllez et al. 2005a, 2005b – longitudinal epidemiological study in pregnant and lactating women in Chile: used in USEPA (2017) to estimate urinary clearance parameters in BBDR model

In our efforts to produce these simulations, it was noted that instructions provided in the USEPA documentation for running the model for different scenarios, and documentation of the rationale for the model parameter values associated with them, are often inadequate and lack transparency; this deficiency is exacerbated by the number of permutations of parameter settings used in the scripts that

generate the results in the document. The complexity of the BBDR model makes it difficult to perform this evaluation, even though it has been conducted by experienced modelers.

Evaluating Stage 2 of USEPA MCLG approach: Stage 2 of USEPA's approach involved evaluating the published epidemiological literature to identify publications that would define quantitative relationships between thyroid hormone levels and neurodevelopmental effects. The USEPA approach was focused on the identification of studies that provided information on levels of fT4 in pregnant mothers during early gestation and the potential for changes in neurodevelopmental outcomes in their offspring. Through targeted literature searching and recommendations from the Science Advisory Board (SAB), a total of 55 studies were identified by USEPA to provide information on altered maternal thyroid hormone levels and offspring development. These studies were divided into three groups to facilitate evaluation:

- Group 1 – studies that may be able to quantitatively describe a relationship between incremental alterations in maternal thyroid hormone levels and alternations in offspring development;
- Group 2 – studies that do not have data from which to derive a quantitative relationship between maternal hormones and offspring neurodevelopment, but instead present only a categorical analysis with thyroid hormones below and above a defined cut point and adverse neurodevelopmental outcomes; and
- Group 3 – studies that present an analysis that is not directly compatible with BBDR output.

Of the 55 studies, 15 were identified as Group 1, 14 were identified as Group 2, 26 were identified as Group 3. The 15 Group 1 studies were then evaluated further and only 5 were deemed useful by the USEPA for further quantitative analysis to attempt to connect alterations in thyroid hormone levels to alterations in neurodevelopment. in our evaluation, we performed a critical review of the USEPA Stage 2 approach and the study summaries provided in USEPA (2017), considering the most recent recommendations from the National Research Council (NRC 2014) on systematic review of the literature and evidence integration.

RESULTS

Evaluation of the Perchlorate BBDR Model for Early Pregnancy

The draft MCLG approach (USEPA 2017) is based on a hypothesized mode of action (Figure 1) for neurodevelopmental outcomes resulting from development of hypothyroxinemia from perchlorate-induced inhibition of iodide uptake in the thyroid. As noted in USEPA (2017):

> "Thyroid hormones are essential for the development and differentiation of the developing brain. The brain and spinal cord begin development in the first half of the first trimester. fT4 passes through the blood-brain barrier via multiple, specific transporter proteins. Next, T4 is converted to T3 by the developing glial cells and then transported to neurons. T3 then interacts with nuclear receptors to tightly regulate gene expression so that neurogenesis, synaptogenesis, neuronal migration, cell differentiation, and myelination are developmentally appropriate. Deficiencies in thyroid hormones through iodine deficiency, congenital hypothyroidism, or maternal hypothyroidism/hypothyroxinemia can result in neurological impairments and intellectual deficits (Morreale de Escobar, Obregón, & Escobar del Ray 2000)."

As recommended by the USEPA SAB (2013), the USEPA extended a published BBDR model for perchlorate induced hypothyroxinemia in late gestation (Lumen et al. 2013; Lumen and George 2017a, 2017b) to address the sensitive population of concern for exposure to perchlorate: the fetuses of hypothyroxinemic women during early pregnancy (Figure 2). These concerns were motivated by new studies (Steinmaus et al. 2016), suggesting an association between perchlorate exposure and decreased levels of free thyroxine (fT4) in pregnant women. Because the fetus is entirely dependent on maternal thyroid hormones for neurodevelopment in early gestation (Clewell et al. 2007; Howdeshell 2002), the endpoint of interest was defined as reduction in maternal fT4 in early pregnancy and the perchlorate BBDR models were extended to describe hormone homeostasis during gestation. Expansion of the original models of perchlorate and iodide (Clewell et al. 2007) to predict the impact of perchlorate exposure on fT4 during early pregnancy, however, is complicated by the significant variability in the levels of fT4 in the general population and the challenges in measuring fT4, as well as the dynamics of changing hormones through the course of gestation and the uncertainty in identifying the level of alteration that may lead to hypothyroidism and fetal effects.

224

225 According to the "American Thyroid Association Task force on Thyroid Disease During Pregnancy and
226 Postpartum", isolated hypothyroxinemia is defined as a normal maternal TSH concentration in
227 conjunction with fT4 concentrations in the lower 5th or 10th percentile of the reference range
228 (Stagnaro-Green et al. 2011). USEPA (2017) has also focused on selected percentiles of the reference
229 range; however, reference ranges can vary from population to population according to the *2017*
230 *Guidelines of the American Thyroid Association for the Diagnosis and Management of Thyroid Disease*
231 *During Pregnancy and Postpartum* (Alexander et al. 2017). Even within US populations and across
232 ethnic groups, the 2.5th percentile can vary by up to 2 pmol/L or approximately 20% (9.3-11.4
233 pmol/L as reported by Alexander et al. 2017).

234 The variation in fT4 reported in the published literature during early pregnancy is provided in USEPA
235 (2017), Appendix A, Figure A-33 and reproduced in Figure 3. The levels of fT4 during early
236 pregnancy, based on the studies identified by USEPA (2017), appear to range from approximately 13-
237 17 pmol/L. This range is consistent with the range of baseline fT4 means reported in the Greer et al.
238 (2002) study of approximately 1.1 – 1.3 ng/dL (14 - 17 pmol/L). However, the 50th percentile BBDR
239 model predictions at zero dose perchlorate and 170 µg/day iodine intake are approximately 10 pmol/L
240 at gestation weeks 12, 13, and 16, considerably below these reported values.

241

242 Measuring fT4 in the presence of high concentrations of bound T4 is challenging, especially in
243 conditions where binding proteins are altered such as during pregnancy (Alexander et al. 2017).
244 Measurement techniques are prone to inaccuracy during pregnancy due to disruption of the original
245 equilibrium. The 95% fT4 reference intervals decrease gradually with advancing gestational age: from
246 1.08– 1.82 ng/dL (approximately 13.9 – 23.5 pmol/L) in week 14 to 0.86–1.53 ng/dL (approximately
247 11.1 – 19.8 pmol/L) in week 20 (Alexander et al. 2017).

248 Extending the thyroid BBDR model to address early gestation is particularly challenging due to
249 the complex interaction between thyroid homeostasis and gestational development.
250 Considering the addition of TSH feedback dynamics, and an adjustment factor to match
251 specific population percentiles, there is reason for concern regarding the uncertainty of the

revised model predictions under low iodide intake conditions. Some of these concerns are highlighted below:

Description of hCG dynamics: Human chorionic gonadotropin (hCG) levels rise in early pregnancy and this in turn increases both sodium-iodide symporter (NIS) uptake activity and T4 production. hCG is structurally similar to TSH and, like TSH, increases thyroidal iodide uptake and thyroid hormone synthesis by binding to the thyroid-stimulating hormone receptor (TSHR) (Hoermann et al. 1994). In the model, hCG levels are calculated as a function of gestational age, using an equation for the parameter HCGREG (Figure 4, purple curve), and these changing levels are used to increase the rate of T3 and T4 production as a function of the hCG concentration:

$$HCGreg = 1 + 0.00354*hCG$$

The variation of hCG over the duration of gestation is based on direct measurements of hCG in pregnant women (Korevaar et al. 2015). However, the concurrent increase in thyroidal iodine uptake is described in the model based on an empirical relationship between gestational age in weeks (GW) and radioactive iodide uptake, using an equation for the parameter VCHNG (Figure 4, green curve):

$$VCHNG(GW) = 1 + 0.076 \cdot GW - 0.0025 \cdot GW^2$$

Thus the model does not correctly attribute the gestational control of NIS uptake to hCG, when in fact both uptake and hormone synthesis respond to the same changes in hCG (Pesce and Kopp 2014). By using different equations for the time-dependence of hCG-stimulated uptake and hormone production (Figure 4) the model decouples processes that are fundamentally linked by their biology. Figure 4 depicts the time-course of the parameters controlling changes in iodide uptake (VCHNG) and hCG hormone levels (HCGreg) over the course of gestation. While the biology indicates a proportional relationship between the two parameters, the equations used in the model are not parallel. Elucidating the impact of this decoupling is challenging, and is beyond the scope of this review, since it would have to be investigated at a large number of time-points throughout pregnancy and under different conditions of iodine intake, but the disparity between the model description and the underlying biology justifies caution regarding its predictions of T4 and TSH at different gestational ages, as these parameters govern hormone production and

release. We address the impact of the discrepancy between the time-courses for HCGREG and VCHNG in a later section.

Damping of TSH response: The USEPA (2017) BBDR model includes a parameter, pTSH (power to which the ratio of current TSH to the TSH set-point is raised), that reduces the response of the thyroid to increases in TSH:

$$TSHreg = (TSH/TSH_0)^{pTSH}$$

Using this equation, a pTSH exponent of 0 would represent no control of thyroid function by TSH and an exponent of 1 would represent a linear response of thyroid function to changes in TSH. In their calculations of the effect of perchlorate on the prevalence of hypothyroxinemic pregnant women, the USEPA (2017) use a pTSH exponent of 0.398, which results in a response to TSH that is substantially less than linear, an assumption that is inconsistent with the fundamental biological relationship between TSH and thyroid hormones (production and release of T3 and T4), effectively decoupling a relationship that has been well established in the medical, pharmacological and toxicological communities. USEPA (2017) describes the rationale for this parameter: "The NHANES data do not show a clear correlation between TSH and fT4, so within that data set they vary independently. One could assume, therefore, that individuals with an average fT4 and high TSH have that combination because their thyroid has a weak response to TSH, and vice-versa." To address this concern, USEPA (2017) estimated a lower and upper bound for pTSH as (median TSH)/(97.5th percentile TSH) = 0.398 and (median TSH)/(2.5th percentile TSH) = 3.09, respectively, with a median value of pTSH = 1. Thus, this parameter is used to attempt to represent disease states where the individual's thyroid is either exquisitely sensitive or insensitive to TSH stimulation. At lower values, this parameter reduces the impact of TSH on the Vmax for thyroid iodide uptake as well as the rate constants for T4 and T3 production in the thyroid. However, the USEPA (2017) also states that: "The coefficient, pTSH, is included…to allow for tuning of the strength of the TSH feedback, but in practice model simulations versus data appear quite adequate with pTSH=1." Concerns about this parameter are two-fold. First, the complexity of the model and various runtime scripts makes it nearly impossible to determine the use of this

parameter during some of the model assessment and risk assessment simulations presented in USEPA (2017). Second, using point estimate population level data to define the quantitative temporal relationship between two fundamentally linked processes at the individual level is scientifically inappropriate. To understand the biological feedback within a single individual (i.e. to determine the relationship of TSH to T3/T4 and Vmax for a hypothyroid or hyperthyroid individual), matched samples would be needed for TSH, T3 and T4. This information – to our knowledge – is not available from NHANES. Thus, the epidemiological point estimate data are being used well beyond its domain of applicability to predict the quantitative outcome of disease states.

Calibration of hormone production rates: The model uses a baseline first-order constant calibrated to NHANES 2007-2012 median, 10th, or 90th percentile non-pregnant data (fT4, fT3, T4 and T3 concentrations). The model parameter for the rate of production of T4 (KProdT4F) for the median NHANES calibration used in USEPA (2017) is 6.25*10-7 /hr/$kg^{0.75}$ (their Table A-2), which is 4-fold lower than the value of 2.45 x 10-6 estimated for the published model (Lumen et al. 2013), which was based on the data of Nicoloff et al. (1972). However, the use of a T4 production rate that is lower than the published value is not adequately justified, given the importance of this parameter, which has a direct impact on predictions of fT4 changes, the intended application of the model. This baseline value is then scaled in pregnancy through GW 16 (peak occurring ~ GW 9) based upon placental hCG increase over this time, according to the linear relationship from Glinoer (1997): hCGreg = 1 + 0.00354 x hCG.

Affinity of NIS Iodine uptake: The model uses a Km for perchlorate binding to the NIS (KmNIS_P) that is 3-fold lower than the value estimated by Lumen et al. (2013) (i.e. a 3-fold higher affinity). Specifically, the new Km represents the 2.5th percentile lower confidence limit of the population median based upon the USEPA (2017) reanalysis of Greer et al. (2002). The median value (50th percentile = 0.73 µM) is similar to that obtained from a re-analysis of *in vitro* binding data, 0.59 µM (Schlosser 2016); the use of a value of KmNIS_P = 0.489 µM makes perchlorate 3 times more effective at competitive inhibition of NIS compared to the model of Lumen et al. (2013). This revision to the Km in USEPA (2017) necessitated revisions to the Vmax (VmaxNISF_thy_P) and urinary excretion parameters (CLFUP) (Table 1 of USEPA 2017), further affecting the model's

sensitivity to changes in perchlorate dose, particularly under conditions of low iodide. Thus, The USEPA (2017) BBDR model predicts much greater effects of perchlorate on iodide uptake than any previous version of the model, without justification for re-estimating these parameters rather than using the published values.

Assumptions regarding thyroidal iodide storage: Plots of NHANES 2007-2012 data for non-pregnant women demonstrated little relationship between iodine intake and fT4, even at iodide intake levels below 75 µg/day (Figure A-54 of USEPA 2017; reproduced in Figure 5a). USEPA (2017) used data on the relationship between thyroidal iodide stores (mg) and iodine intake from Delange (2000), which assumes depletion of fT4 at iodide intake levels below 100 µg/day. As is clear from Figure 5b, this assumed model behavior at concentrations below 100 µg/day, which drives model predictions at low intakes, is inconsistent with the NHANES data and could result in overprediction of fT4 responses at moderately low intakes of iodide, including the ranges simulated in the USEPA report. This possibility was investigated in this evaluation and the results are discussed in the next section.

Evaluation of BBDR Model Behavior

Comparison to the Steinmaus et al. 2016 Results

In Appendix B of USEPA (2017), a comparison of the predicted changes in both fT4 and TSH from the BBDR model were compared to the results reported by Steinmaus et al. (2016). The Steinmaus et al. (2016) study was conducted to evaluate the potential for perchlorate exposure to impact thyroid hormone levels in pregnant women (any trimester) in San Diego. They reported an effect of perchlorate on fT4 levels to be similar among women with both low iodine (<100 µg/day) and normal (100-300 µg/day), with a greater effect of perchlorate observed among pregnant women in the high iodine intake group (>300 µg/day). They further noted that this result is in contrast to some previous results from NHANES (Blount et al. 2006) and may be due to the overall iodine sufficiency in the studied population or the fairly long time between urine iodine and serum thyroid hormone sample collection (about 9 weeks).

The comparison of the predicted fT4 changes from the BBDR model and the Steinmaus et al. (2016) results associated with changes in perchlorate dose are reported in Figure B-1 of Appendix B of USEPA (2017) and reproduced in Figure 6. This comparison, which we were able to reproduce using the

366 USEPA (2017) BBDR model, clearly highlights the differences between the model predictions and the
367 published human data. The USEPA (2017) BBDR model simulations with normal iodine intake (170
368 µg/day) demonstrate no change in fT4, which is consistent with other studies in which no impact on
369 fT4 has been observed at doses up to 7 µg/kg/day perchlorate (Greer et al. 2002; Braverman et al.
370 2006). The USEPA (2017) BBDR model greatly under-predicts the changes in fT4, even in the
371 scenario with low dietary iodine intake (75 µg/day), in comparison to the changes reported by
372 Steinmaus et al. (2016). This discrepancy raises concerns about the ability of the USEPA (2017)
373 BBDR model to predict changes in fT4 associated with chronic perchlorate exposure during pregnancy.

374

375 *Greer et al. 2002 – 14 day human controlled perchlorate dosing study*

376 The Greer et al. (2002) study was conducted to establish the dose-response in humans for perchlorate
377 inhibition of thyroidal iodide uptake and any short-term effects on thyroid hormones following
378 exposure for male and female volunteers to perchlorate in drinking water at doses of 7, 20, 100 or
379 500 µg/kg/day for 14 days. The results of this study have previously been relied upon by the USEPA
380 (2005) to derive a reference dose (RfD) and to determine health reference levels (HRLs). The results
381 of this study indicate a decrease in iodide uptake following exposure to a dose of 20 µg/kg/day, but no
382 effect on hormone levels, including fT4 and TSH, at the highest dose tested. A No Observed Effect
383 Level (NOEL) of 7 µg/kg/day was determined based on these results, and an RfD of 0.7 µg/kg/day
384 was adopted, based on NAS recommendations, with the application of an uncertainty factor of 10 for
385 intraspecies variability or sensitive subpopulations.

386 Consistent with the results of the study, our simulations of the adult exposures reported in Greer et al.
387 (2002) with the BBDR model (Table 1) indicated no significant change in fT4 at doses up to 500
388 µg/kg/day. However, predicted concentrations of fT4 are lower than those measured by Greer et al.
389 (2002). The model simulation reported in Table 1 was run with an iodine intake of 90 µg/day, as this
390 was the value USEPA (2017) used in the Greer_test.m script provided with the BBDR model code.
391 However, 90 µg/day is not consistent with the 170 µg/day value USEPA (2017) reports as
392 representing a sufficient intake and USEPA's (2017) documentation does not indicate why a lower
393 value was used for the individuals in the Greer study. Simulation of iodide uptake inhibition (RAIU)
394 appears to over-predict the reduction in uptake compared to measured values, though the qualitative

increasing trend of inhibition with dose behaves appropriately. This discrepancy may result from the low iodine intake chosen by USEPA (2017), or a number of other decisions made in the model revisions, including the reduced Km parameter value. It is unclear why the parameters governing iodide inhibition were altered from previous models that successfully predicted inhibition of iodide in human subjects (Clewell et al. 2007; Merrill et al. 2003; Lumen et al. 2013). Given that iodide inhibition is the obligatory precursor to all downstream effects in the USEPA's proposed mode of action for perchlorate, it would be expected that any changes to the model that lead to reduced accuracy in the prediction of iodide inhibition would be accompanied by substantial support. However, no such support is provided in USEPA (2017) for the changes in the key parameters and the resulting effect on iodide inhibition predictions.

Table 1. Simulation of the Greer et al. (2002) Perchlorate Study

Dose	RAIU (%)		fT4 (pM)	
(µg/kg/d)	Simulated	Measured	Simulated	Measured
0	100	100	10.33	-
7	89	98.2	10.33	-
20	74	83.6	10.32	16.09
100	37	55.3	10.31	15.26
500	11	32.9	10.30	15.44

Braverman et al. 2006 – 6 month human controlled perchlorate dosing study

The Braverman et al. (2006) study was conducted to determine whether prolonged exposure (6 months) of adults to low levels of perchlorate (0.5, 1.0 or 3.0 mg/day) would perturb thyroid function. The study included a small number of individuals (n=13); however, iodine levels were comparable with those of the general population. The authors noted the limitations of the small sample size, but concluded that the results suggested that healthy, euthyroid individuals, with normal levels of iodine intake, can tolerate chronic exposure to perchlorate at doses of up to 3 mg/day (approximately 40 µg/kg/day) without any effects on thyroid function, including inhibition of iodine uptake.

The Braverman et al. (2006) study was simulated as part of the current evaluation using the BBDR model and predicted T3 and TSH levels were compared to the reported measurements (Table 2). fT4

was not compared because it was not clear how to convert the T4 index reported in the study to a concentration and vice versa. As with the Greer et al. (2002) simulation, 90 µg/day was used for iodine intake. Baseline T3 and TSH are similar to the measured values. But, as was seen with fT4, the model fails to predict the observed changes in hormone levels in the adult subjects.

Table 2. Simulation of Braverman et al. (2006) perchlorate study.

Dose	T3 (nM)		TSH (mIU/L)	
(µg/kg/d)	Simulated	Measured	Simulated	Measured
0	2.63	2.49	1.51	1.20
7	2.63	2.51	1.52	1.60
43	2.62	1.77	1.53	2.60

Téllez Téllez et al. 2005a, 2005b – Chilean epidemiological study in pregnant women

Téllez Téllez et al. (2005a, 2005b) reports the results of a longitudinal epidemiological study among pregnant women from three cities in Chile exposed to concentrations of perchlorate as high as 114 µg/L in the public drinking water. The focus of the study was to evaluate maternal thyroid function during pregnancy, neonatal thyroid function and developmental status at birth, and breast milk iodine and perchlorate levels during lactation. The National Academy of Sciences (2005) has reviewed this study in the context of health implications for perchlorate ingestion and concluded this study should be considered in the evaluation of the US experience with perchlorate in drinking water. The total iodine nutrition among this cohort was also noted to be similar to that of US pregnant women (Téllez Téllez et al. 2005a); therefore, this study should be a key consideration in evaluating the relationship between perchlorate exposure, changes in fT4 in pregnant women and developmental status; however, it was not considered in Stage 2 of the USEPA (2017) assessment because it pre-dated the cutoff used by USEPA in their review (2010).

Results from this study indicated no effect on thyroid levels in early pregnancy, late pregnancy, or neonates at birth related to perchlorate in drinking water at concentrations up to 114 µg/L. Given these findings, this study provides a reasonable dataset for validating the impact of high perchlorate exposure concentrations in drinking water on potential changes in fT4 or TSH.

We also ran the (USEPA 2017) BBDR model to simulate the Téllez Téllez et al. (2005a, 2005b) drinking water study (Table 3). The BBDR model predictions of fT4 for GW 13-16 are consistent with the negative results of the study, though the predicted concentrations are lower than those observed. This is not a strong validation of the model given the weak trend of changes in hormone levels seen in comparisons to other studies.

Table 3. Simulation of the Téllez Téllez **et al. 2005a, 2005b study of pregnant women exposed to perchlorate via drinking water.**

Dose	**fT4 (pM)**	
(µg/kg/d)	**Simulated**	**Measured**
0.01	9.74	12.5
0.08	9.73	12.2
2	9.69	12.7

Summary: Evaluation of Model Behavior

Our simulations of the Greer et al. (2002) and Braverman et al. (2006) studies with the BBDR model indicate that thyroid hormone levels are relatively insensitive to inhibition of thyroid iodine uptake by perchlorate exposures as high as 7 µg/kg/day. Moreover, our simulations of the Téllez Téllez et al. (2005a, 2005b) study with the BBDR model do not predict an effect on fT4 from exposures to perchlorate at up to 2 µg/kg/d, consistent with the fact that the exposures were demonstrated to be without effect to pregnant women in the study. However, the USEPA (2017) BBDR modeling analysis (Table 4, taken from USEPA 2017)predicted population-level changes in fT4 deficiency during the first trimester at perchlorate exposures nearly an order of magnitude lower (0.3 µg/kg/d) . This discrepancy suggests that the metric used in the USEPA (2017) approach to assess population-level effects of perchlorate, i.e., a 1% or 5% increase the proportion of thyroxinemic mothers in early pregnancy assuming that all individuals have a low (75 µg/day) iodine intake and an inadequate TSH response (pTSH = 0.398 vs. 1), may be overly conservative.

Table 4. Summary of Results for the Amount of Perchlorate Needed to Increase the Proportion of Hypothyroxinemic, Low Iodine Individuals by a Defined Percentage (with hypothyroxinemia defined as fT4< 10th Percentile) (USEPA 2017)

Gestational Week	fT4 (pmol/L) at the Hypothyroxinemic Cut Point (i.e. 10th Percentile of 170 µg/day Iodine Intake Group) (Column 1)	Corresponding Percentile in 75 µg/day Iodine Intake Group (Column 2)[a]	Perchlorate Dose (µg/kg/day) Associated with a 1 Percent Increase in Proportion Hypothyroxinemic (Column 3)[a]	Perchlorate Dose (µg/kg/day) Associated with a 5 Percent Increase in Proportion Hypothyroxinemic (Column 4)[a]
12	8.80	48.4	0.4	2.2
13	8.78	47.9	0.4	2.2
16	8.63	52.6	0.3	2.1

[a] Results based on central effect estimates, pTSH in BBDR model set to 0.398

457

458 ***Evaluation of the effect of model assumptions on predicted PODs***

459 In order to assess the potential quantitative impact of some of the uncertainties in the BBDR
460 model, we compared model predictions of percent change in fT4 and TSH for a range of
461 perchlorate concentrations using two alternative parameterizations: (1) the parameterization
462 used by the USEPA (2017) to generate their Table 3, and (2) replacing the equation for
463 HCGREG with the equation for VCHNG (in order to provide an appropriately coupled response
464 to hCG stimulation of thyroidal iodine uptake and thyroid hormone production), and also
465 setting pTSH = 1 (the nominal value, as opposed to the lower-bound value of 0.398 used by
466 the USEPA). The simulations (Table 5) were performed with the model calibrated to either the
467 median population thyroid hormone levels (using the script medset.r) or a low (thyroxinemic)
468 population defined as fT4 < 10th percentile (using the script lowset.r). When predicting the
469 effect of perchlorate exposure on fT4 for the median population there is not a significant
470 difference between the USEPA results and the alternative parameterization; however, the
471 USEPA model parameterization results in more than a factor of 2 greater sensitivity of TSH
472 levels to perchlorate compared to the alternative parameterization. This difference is primarily

473 due to the change in pTSH. On the other hand, when predicting the effect of perchlorate
474 exposure on hypothyroxemic individuals, both fT4 and TSH responses to perchlorate exposure
475 are significantly lower using the alternative parameterization. Thus, the parameters that were
476 altered in the recent revision of the model (VCHNG, HCGreg, pTSH, KmNiS_p) increase the
477 predicted effect on thyroid hormone levels compared to the expected response with the well-
478 validated precursor event of iodide inhibition. The sensitivity of the prediction to changes in
479 these parameters, and the disconnect between the prediction of iodide inhibition and thyroid
480 hormone levels, calls for better justification – and evaluation – of the given parameter values.

Table 5. Predicted fT4 and TSH Concentrations at Various Doses of Perchlorate for 75 µg/day Iodine Intake

Perchlorate Dose (µg/kg/day)	fT4 (pmol/L) (% Change from 0 Dose)				TSH (mIU/L) (% Change from 0 Dose)			
		USEPA[0]	VCHNG + pTSH[1]	VCHNG + pTSH[1]		USEPA[0]	VCHNG + pTSH[1]	VCHNG + pTSH[1]

481 **Review of Literature Linking BBDR Results to Neurodevelopment Outcomes**

482 Chapter 5 of USEPA (2017) focuses on the SAB's recommendation to "Identify literature and conduct
483 analyses to support the model outputs for the downstream steps" from the BBDR's predicted changes
484 in thyroid hormones following exposure to perchlorate. Specifically, Chapter 5 was developed to
485 present the process USEPA (2017) used to identify literature to support the draft approach for
486 derivation of the MCLG for perchlorate. USEPA (2017) states, "Based on the recommendations of

487 previous peer review panels, USEPA assumed that changes in thyroid hormone levels would be
488 expected to lead to neurodevelopmental outcomes", and because of this assumption, a complete
489 systematic review of the body of literature on this topic was not performed. Instead, a "focused
490 review of the published literature" was conducted.

491 The approach is inconsistent with recent recommendations from the National Research Council (NRC
492 2014) regarding systematic review and evidence integration. These recommendations are currently
493 being incorporated into the USEPA's Integrated Risk Information System (IRIS) process and USEPA
494 has recently released scoping and problem formulation materials for several new Integrated Risk
495 Information System (IRIS) assessments, including ethylbenzene (USEPA 2014a), and naphthalene
496 (USEPA 2014b). The approach applied in these assessments is intended to follow recommendations
497 provided by the National Research Council (NRC 2013). While development of MCLGs are not part of
498 the IRIS process, the application of systematic review principles in the identification of studies to
499 define the relationship between fT4 and neurodevelopmental effects, is needed. The application of
500 these principles would not only assist in defining the highest quality studies to address a specific
501 research question, they also provide a way to integrate all of the available evidence for the specific
502 research questions raised by the SAB. Systematic reviews include the formulation of a specific
503 question to be addressed and developing a protocol that specifies the methods that will be used to
504 address the question. While a broad research question can lead to a large systematic review, if the
505 research question is limited, such as in the case of perchlorate, then the systematic review becomes
506 more focused.

507 For the USEPA (2017) draft MCLG approach, a systematic review question could have been easily
508 developed based on the SAB recommendation (i.e. "Identify literature and conduct analyses to support
509 the model outputs for the downstream steps") and the protocol would simply be focused on the
510 methods for conducting the systematic review to address this very focused systematic review question
511 in a transparent manner. Transparency being defined by USEPA as "sufficient information will be
512 available to understand the scientific rational behind decisions, as well as, reproduce methods used to
513 identify and evaluate data". However, in the case of the literature identified for consideration in the
514 draft MCLG approach for perchlorate, a well-defined protocol for all steps of the process has not been
515 developed and therefore is inconsistent with the recommendations of the NRC (2013):

> *"A priori decisions and a predefined protocol are critical during the systematic review process (Berlin and Colditz 1999; Dickersin 2002); the protocol should describe the following steps: the research question, the search strategy and data sources, the study inclusion and exclusion criteria, the data to be abstracted and derived from the original studies (such as sample size, exposure and outcome assessment methods, and confounders evaluated), the criteria and methods for pooling effect estimates and measures of variability among studies. Systematic reviews and meta-analyses need to be replicable; other investigators following the same steps should be able to identify the same articles, abstract the same data, and reach similar conclusions."*

At each step of the process for identifying studies for use in the development of the MCLG approach for perchlorate, a detailed set of criteria is needed. For example, if decisions are made to include or exclude any studies, there should be very detailed criteria indicating why studies were included or excluded and it should be specified prior to the initiation of the literature searching process. The criteria for each step should be described in such a way that an independent reviewer could use it to replicate the results of the literature search and review; however, there are several areas in the USEPA (2017) draft MCLG approach for perchlorate where this level of detail is lacking, making it difficult for an independent reviewer to replicate the results.

Systematic Review Research Questions

An overall hypothesis or systematic review research question should be developed that is based on the SAB recommendation to clarify the focus of the review and the linkage between altered maternal fT4 (as predicted by the BBDR model) and the potential for adverse neurodevelopmental effects in offspring. Some additional explanation as to how USEPA arrived at the specific neurodevelopmental outcomes of concern should be provided.

Searching the Published Literature

While the literature search key words are presented in the USEPA (2017) report, there is a lack of explanation as to the reasoning behind the focus on the outcome of concern. The research question should be used to develop the literature search. The major points used or considered in developing

544 the literature search strategy should be presented. In addition, there should be a detailed explanation
545 of the criteria used to screen the literature search results. Furthermore, USEPA (2017) does not
546 report the details of the literature search results. For each search string reported in Table 9 of the
547 USEPA (2017) report, a total number of citations identified should be reported. In addition, the
548 criteria used to screen the original search results should be clearly reported in the document.
549 Essentially, each step of the literature search and review should be reported in such a way that any
550 independent party could easily reproduce the results reported in Chapter 5 of USEPA (2017). The lack
551 of this type of information does not allow the reader to determine if any key studies may have been
552 removed from consideration.

553 *Literature Screening Approach and Selection of Key Studies*

554 USEPA (2017) states that a 3 step approach was used to identify studies for consideration in the
555 development of the approach for derivation of the MCLG for perchlorate. The approaches utilized by
556 USEPA (2017) to identify the epidemiological studies for this evaluation were strictly focused on the
557 appropriateness of the quantitative data for consideration in combination with the output of the BBDR
558 model. Group 2 (studies with categorical analyses only) and Group 3 (studies with analyses not
559 directly compatible with BBDR output) studies were apparently eliminated from consideration in the
560 assessment. While not directly compatible with BBDR modeling output, it is possible that these
561 studies may provide information important in understanding the potential relationship between
562 changes in thyroid hormones and the potential for neurodevelopmental effects, as well as potential
563 key confounders.

564 While 15 studies were identified in Group 1, only 5 of these were determined by USEPA to include
565 analyses that could be used to connect the results of the BBDR model to incremental changes in
566 adverse neurodevelopmental effects. A clearly defined set of inclusion and exclusion criteria should be
567 provided to clearly convey to the reader why the other 40 studies in Groups 1, 2, and 3 were not
568 considered. In addition, studies that provide no evidence of an inverse relationship between
569 perchlorate exposure and serum thyroid function (e.g. Ghassabian et al. 2014; Modesto et al. 2015;
570 Moleti et al. 2016; Noten et al. 2015) should also be considered to not only understand why these
571 results are in contrast to the potential research question, but also that the overall weight of evidence
572 can be determined. It is possible that the majority of studies provide evidence that critical factors that

573 are not reported in some of the available studies may explain the reported changes in serum thyroid
574 function.

575 *Assessment of Study Quality and Risk of Bias*

576 According to recent recommendations from the National Research Council (NRC 2014), the National
577 Toxicology Program's (NTP) Office of Health Assessment and Translation (OHAT) method for the
578 assessment of study quality and risk of bias of the literature (NTP 2015) is one method that should be
579 considered for qualitative and quantitative assessments. "An assessment of study quality evaluates
580 the extent to which the researchers conducted their research to the highest possible standards and
581 how a study is reported. Risk of bias is related to the internal validity of a study and reflects study-
582 design characteristics that can introduce a systematic error (or deviation from the true effect) that
583 might affect the magnitude and even the direction of the apparent effect" (NRC 2014). Each study
584 meeting inclusion criteria in Group 1, 2, and 3, should be evaluated against a predetermined set of
585 study quality and risk of bias criteria and the results of this evaluation should be presented in the
586 perchlorate MCLG approach report.

587 Uncertainties Critical to Characterizing Changes in Thyroid Hormone Levels in Pregnant Women
588 Associated with Neurodevelopmental Changes in Offspring

589 The draft MCLG approach presented in USEPA (2017) to predict doses of perchlorate that would result
590 in per unit changes in neurodevelopmental measures, is, as noted by USEPA (2017), "…dependent
591 upon predictions from the BBDR model, the derivation of the distribution of fT4, and the evaluations of
592 the relationship between fT4 and neurodevelopment. Each of these steps has inherent uncertainties
593 associated with it."

594 A major source of uncertainty is related to the five studies in Group 1 with data that could be used to
595 quantitatively describe the relationship between thyroid hormone levels in early pregnancy and
596 changes in neurodevelopment (Pop et al. 1999, 2003; Finken et al. 2013; Korevaar et al. 2016;
597 Vermiglio et al. 2004). None of these five studies relied upon data from US populations or have been
598 demonstrated to have iodine intake similar to US populations. Yet according to the American Thyroid
599 Association (Alexander et al. 2017), the reference range of both TSH and fT4 in pregnant women
600 varies depending upon ethnicity. While two studies in Group 1 focused on population groups within

601 the United States, neither were considered for the model because T4 and not fT4 was measured in the
602 pregnant females (Oken et al. 2009) and the relationship between fT4 and neurodevelopment was
603 evaluated in late pregnancy and did not reach statistical significance (Chevrier et al. 2011). USEPA
604 (2017) (Section 6.5.1) states "there is no reason to believe that the impact of fT4 on
605 neurodevelopment would differ by country, unless there is a substantial difference in iodine intake".
606 While USEPA (2017) does make an effort to evaluate changes in iodine intake in women from various
607 populations, including the US, there are not substantial data reported in the peer-reviewed literature
608 to validate the conclusions that the impact of fT4 on neurodevelopment would differ by population or
609 uncertainty in iodine intake levels would have an impact on the derivation of the MCLG. This is
610 inconsistent with data from the American Thyroid Association (Alexander et al. 2017) that suggest
611 variability in the distribution of thyroid hormone levels across populations and even within ethnicities
612 within a single population.

613 USEPA (2017) also notes that all five studies used for quantitative analysis relied on a one-time fT4
614 level during pregnancy (Section 6.5.5). The influence of changes in maternal fT4 on fetal brain
615 development is likely greatest during early pregnancy. The variability in maternal fT4 levels during
616 pregnancy and the lack of measurement of fT4 at time points throughout pregnancy in the studies
617 provides a substantial data gap and lack of information needed to validate some of the assumptions
618 relied upon in the development of the BBDR current model as well as the resulting predictions of the
619 model. As stated in USEPA (2017),

620 *"Circulating T3 and T4 levels in an individual are maintained within a narrow range by*
621 *a negative feedback loop with TSH from the pituitary and TRH from the hypothalamus*
622 *that operates around a "set-point." This set-point is different from individual to*
623 *individual, which generates a population variance in blood levels of thyroid hormone*
624 *that is considerably broader than the individual variance (Andersen, Pedersen, Bruun,*
625 *& Laurberg 2002). Therefore, in euthyroid individuals, serum T4 and T3 fluctuate*
626 *within a fairly narrow range (about 10% of the population variance), maintained by*
627 *the negative feedback relationship with serum TSH from the pituitary gland. This*
628 *normal variation creates a situation where single measures of free or total T4 and TSH*

629 *are a somewhat imprecise measure of an individual's average T4 and TSH*
630 *concentrations (Andersen et al. 2002)."*

631 Several other areas of uncertainty are also highlighted by USEPA (2017). Specifically, USEPA
632 (2017) noted that none of the five studies carried forward provided iodine intake levels
633 (Section 6.5.3), which adds significant uncertainty to the estimates. Three of the 5 studies
634 (Pop et al. 1999, 2003; Vermiglio et al. 2004) also have populations of less than 30
635 decreasing the statistical power of the studies (section 6.5.4) relied upon for establishing the
636 relationship between changes in fT4 and neurodevelopmental changes. USEPA (2017) also
637 noted uncertainties in regard to the analytical methods used to evaluate fT4 levels and while
638 approaches are being introduced to standardize analytical methods, results at different time
639 points and from different countries may vary considerably due to differences in analytical
640 procedures (USEPA 2017). USEPA (2017) also notes that "there is uncertainty regarding the
641 true fT4 levels at various percentiles in the distribution around the median output from the
642 BBDR model. This is exemplified by the fact that in this analysis larger unit changes are being
643 seen with increasing percentiles of fT4 in most analyses." Finally, other confounders such as
644 iron deficiency were not considered in the analysis. Iron deficiency in pregnant mothers,
645 which is noted in approximately 18% of pregnant women in the US (Cantor et al. 2015), may
646 also be associated with hypothyroxinemia (Yu et al. 2015) and failing to directly account for a
647 relationship between iron deficiency and hypothyroxinemia may introduce an uncertainty into
648 this analysis.

649 While all these uncertainties are noted by USEPA (2017), there is no attempt to adjust the
650 draft MCLG approach in any way to account for these uncertainties. Many of these, especially
651 confounders such as iron deficiency in the study population and a lack of information on iodide
652 intake, can have a significant effect in characterizing changes in thyroid hormone levels
653 associated with changes in neurodevelopmental outcomes. In the absence of adequately
654 accounting for these uncertainties, it is difficult to have confidence that BBDR model
655 predictions of small changes in a specific thyroid hormone (e.g. fT4) may accurately predict
656 the potential for neurodevelopmental effects.

The inadequacy of the USEPA (2017) literature review is substantiated by the comments of the External Peer Review for USEPA's Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water (Versar 2018). Comments regarding the USEPA (2017) literature search included:

- "The literature search produced ten studies (that assessed maternal serum FT4 concentrations as a continuous measure which did not observe an adverse effect on offspring neurocognition), as well as those in Group 2 that assessed serum FT4 as categorical measures. Although their inclusion may not necessarily be recommended in the final model, comparison of the estimated effects on the various neurocognitive outcomes with and without these may indeed inform the degree of uncertainty inherent in the present model. Several of the studies in Group 2 were able to demonstrate significant adverse outcomes (Berbel 2009 as one excellent example), and also their more global nature would help support the generalizability of the present model."
- "Excluding these studies lessens the power of the total sample size and thus the ability to detect an association between maternal hypothyroxinemia and any of the offspring outcomes, but provides what may be a somewhat exaggerated estimate of the potential adverse effects of perchlorate exposure. This approach is more conservative, to which there are pros and cons of doing so, toward derivation of a perchlorate MCLG. With this approach, the goal is to minimize exposure to the lowest perchlorate concentration associated with any number of adverse outcomes. I would favor the more liberal public health approach, which is inclusion of all available studies, whether they are positive or negative. Although the perchlorate MCLG may be higher, this latter approach would be consistent with using all available evidence to improve the scientific rigor of the proposed study question."

The peer reviewers also suggested a number of additional peer-reviewed studies that they felt should have been considered to inform BBDR modeling of the quantitative relationship between thyroid hormone levels and neurodevelopmental outcomes:

Function During Pregnancy and the Cognitive Development of Their Offspring: Data from the Controlled Antenatal Thyroid Study. The Journal of Clinical Endocrinology & Metabolism, 99(11): 4291-4298.

In the draft MCLG approach, USEPA (2017) focused on five studies that evaluated the relationship of maternal fT4 and several neurodevelopmental endpoints (IQ, mental development index (MDI), psychomotor development index (PDI), standard deviation of reaction time), based on measurements of fT4 during early pregnancy. Results from previous studies have provided the basis for No Observed Effect Levels (NOELs) for health effects of perchlorate in the development of Reference Doses and currently recommended Health Reference Levels (HRLs), including Greer et al. (2002) in which adult men and women were exposed to perchlorate in drinking water at doses of 0.007, 0.02, 0.1, or 0.5 mg/kg/day for 14 days demonstrated a NOEL for perchlorate inhibition of radioiodide uptake by the thyroid NIS following exposure to 7 µg/kg/day. The point of departure from the Greer et al. (2002) study represents a perchlorate level that precedes the inhibition of iodine uptake by the thyroid. The NAS RfD developed based on the point of departure (POD) from this study is a deviation from the Agency's traditional approach of using a No Observed Adverse Effect Level (NOAEL) for regulatory actions. The NAS's use of a No Observed Effect Level (NOEL) is based on "using a nonadverse effect that is upstream of the adverse effect [which] is a more conservative and health protective approach".

While these studies have not been conducted in pregnant women (the population of interest for the draft MCLG approach), as noted by in USEPA (2017):

> *"…the BBDR model predicts very little difference in non-pregnant and first-trimester response to perchlorate. This likely occurs because the half-life of (organified) iodine in the adult thyroid is around six months, hence the availability of thyroidal iodine in the first trimester pregnant woman is determined to a very large extent by her nutrition and perchlorate exposure several years preceding pregnancy."*

This suggests that a comparison of the current modeling results to those from studies conducted in adults should provide insight into the predictions of the model and the conclusions regarding the changes in thyroid hormone levels that may result in neurodevelopmental effects.

742 The current draft approach for deriving the MCLG assumes any exposure to perchlorate reduces fT4 to
743 some extent (p. 3-17 of USEPA 2017). In addition, linear regression analyses conducted to evaluate
744 the relationship between changes in fT4 and neurodevelopmental effects further assumes any change
745 in fT4 results in some risk of neurodevelopmental effects. These assumptions are in contrast to the
746 results from Greer et al. (2002) in which exposures to perchlorate were as high as 500 µg/kg/day and
747 no impact on thyroid hormone levels was observed. This was true for both men and women. In
748 addition, in a study conducted by Braverman et al. (2006), 6 months of exposure to perchlorate in
749 capsules at doses up to 3 mg/day (approximately 40 µg/kg/day) was reported to have no effect on
750 thyroid function, including inhibition of thyroid iodide uptake as well as serum levels of thyroid
751 hormones, TSH, and Tg in a small group of volunteers.

752 USEPA (2017) notes (p. 6-16) that from results of the literature review, it appears the relationship
753 between maternal fT4 and fetal brain development has a temporal relationship, with this influence
754 likely being greatest in early pregnancy (i.e. prior to mid-gestation). The focus of the evaluation is on
755 gestational weeks 12, 13, and 16, where the mother's fT4 levels will have the greatest impact on the
756 fetus. This should allow for comparison to the model results in pregnant women to results from
757 previous studies focused on identification of perchlorate concentrations that would impact fT4 levels in
758 adult women, such as the Greer et al. (2002) study.

759 Based on the BBDR model predictions, USEPA (2017) estimates that a perchlorate dose of 0.3-0.4
760 µg/kg/day would result in a 1% increase in the proportion of the population with hypothyroxinemia
761 and a perchlorate dose of 2.1-2.2 µg/kg/day would result in a 5% increase in proportion of the
762 population with hypothyroxinemia. These modeling results suggest a potential for a significant change
763 in thyroid hormones, as well as adverse effects on neurodevelopment at doses of perchlorate exposure
764 for which there is evidence that decreases in fT4 are not observed. Based on the mode of action
765 proposed by USEPA (2017), decreases in fT4 and increases in TSH would be prerequisite steps for the
766 potential for neurodevelopmental effects. These changes in hormone levels are not observed in the
767 Greer et al. (2002) study following exposure up to 500 µg/kg/day. The draft MCLG approach suggests
768 population changes in fT4 would be observed that would shift the proportion of pregnant women that
769 would be hypothyroxinemic at doses of perchlorate below the previously defined NOEL (7 µg/kg/day).

Table 6 (Table 39 of USEPA 2017) provides the predicted dose of perchlorate per unit change in neurodevelopmental measure for low iodine intake individuals. Those for IQ are approximately at or above (6.5 – 45 µg/kg/day) the NOEL from Greer et al. (2002) and are associated with decreases in fT4 of 4.3 to 18.7%. The doses associated with other neurodevelopmental endpoints are 1.7 to 3.0 µg/kg/day and are associated with decreases in fT4 of 1.3 to 2.4%. These percent changes in fT4 are very small and considering the potential uncertainty and variability in measuring fT4 levels, there is a lack of evidence that such small changes in fT4 will result in clinical observations. Reference ranges for fT4 are 0.9 – 2.5 ng/dL in infants (0-5 days) and 0.9 – 1.7 ng/dL in adults (> 20 yrs) (https://www.mayomedicallaboratories.com/test-catalog/Clinical+and+Interpretive/8725). Thus, for an adult, at the low end of the reference range, we would expect a change from 0.900 to 0.878 ng/dL, a value that given the number of significant figures in the reference value would not be measurable. The dose of perchlorate estimated to result in a 1% or 5% increase in the proportion of hypothyroxinemic pregnant women is even lower, ranging from 0.3 to 2.2 µg/kg/day. USEPA (2017) findings are contrary to multiple studies in adults and pregnant women (Greer et al. 2002; Braverman et al. 2006; Téllez Téllez et al. 2005a, 2005b) provide robust evidence that no impact on iodine uptake or thyroid hormone levels would be expected at these dose levels. Based on the mode of action proposed by USEPA (2017), these precursor impacts are necessary to generate the neurodevelopmental effects derived from the BBDR model.

Table 6. Predicted Dose of Perchlorate per Unit Change in Neurodevelopmental Measure for Low Iodine Intake Individuals based on Central Effect Estimates at the Median fT4 level (USEPA 2017)

Study	Endpoint	ΔfT4 in pmol/L (% ΔfT4 from 0 dose perchlorate, iodine intake = 75 µg/day)	Dose of perchlorate per unit change in endpoint (µg/kg/day)[a]
Korevaar et al. (2016) Quadratic	IQ	-1.08 (12.2%)	23
Korevaar et al. (2016) USEPA Independent Analysis: Bivariate	IQ	-0.98 (11.1%)	20
Korevaar et al. (2016) USEPA Independent Analysis: Multivariate	IQ	-1.66 (18.7%)	45
Vermiglio et al. (2004)	IQ	-0.37 (4.3%)	6.5
Pop et al. (2003)	MDI	-0.15 (1.7%)	2.2
Pop et al. (2003)	PDI	-0.12 (1.3%)	1.7
Pop et al. (1999)	PDI	-0.12 (1.3%)	1.7
Finken et al. (2013)	SD of Reaction Time	-0.21 (2.4%)	3.0
BBDR model (USEPA 2017)	1% or 5% increase in proportion of hypothyroxinemic pregnant women[b]	1% or 5%	0.3 – 0.4[c] [1%] 2.1 – 2.2[c] [5%]

[a] Based on the regression analysis for the range of fT4 data within each study. Central beta estimates of the low iodide intake population (= 75 µg/day) are presented.

[b] Hypothyroxinemia defined as fT4 < 10th percentile

[c] Range based on gestational week used to perform the analysis (12 to 16 weeks).

DISCUSSION

A critical review of the (USEPA) 2017 report entitled "Draft Report: Proposed Approaches to Inform the Derivation of a Maximum Contaminant Level Goal for Perchlorate in Drinking Water", as well as the BBDR model that was proposed for use in derivation of the MCLG, was conducted. Overall, conducting this review and assessment of the BBDR model was beset by multiple challenges and the effort highlighted a number of uncertainties in the use of the model. The main challenges that the review presented were due to the complexity of the BBDR model itself. The co-authors of this review, who are widely considered to be experts in the area of PBPK and BBDR model development, found it difficult to evaluate the complex interactions of model parameters and their relationship to the predictions of the model. In our efforts to reproduce simulations provided in USEPA (2017), it was noted that instructions for running the model for different scenarios, and documentation of the rationale for the model parameter values associated with them, were sometimes inadequate; this deficiency, which is inevitable in a complex model, was exacerbated by the number of code scripts required to set the parameters used to generate the various results in the document. As a result, the ability to independently verify all aspects of the model were impeded by uncertainties associated with the steps necessary to reproduce figures and tables in the report, or to perform comparisons of model predictions to data for alternative exposure scenarios or studies.

As suggested by C.A.R. Hoare in his 1980 ACM Turing Award Lecture: "There are two ways of constructing a software design: One way is to make it so simple that there are obviously no deficiencies and the other way is to make it so complicated that there are no obvious deficiencies." By their nature, BBDR models are seldom simple; to the extent that BBDR models attempt to describe complex biological systems they will inherently be difficult to comprehend. The criticisms of the perchlorate PBPK model in this case study are not meant to suggest that the model is incorrect or un-useful, and they should not be taken as criticisms of the utility of BBDR modeling in general. Used appropriately, BBDR models can provide important information for better risk assessment decision-making. The issue that needs to be addressed in each case is whether a BBDR model is fit for the intended purpose of using it in the risk assessment.

The first use of PBPK modeling in risk assessments dates back to the 1980s (USEPA 1987) and yet the application of PBPK modeling to replace default dosimetry remains controversial, primarily due to

818 concerns regarding model uncertainty. To address these concerns, the OMB (2007) memorandum on
819 risk analysis recommended the presentation of results from multiple dose-response approaches to
820 provide a more robust risk characterization. In this scenario, a fit-for-purpose BBDR model can
821 provide information on the most scientifically plausible risk estimate for comparison with the results of
822 default approaches (Clewell et al. 2008). Consistent with this OMB recommendation, one focus of our
823 evaluation was determining how the results of the BBDR modeling could inform the likelihood that the
824 current perchlorate guideline (USEPA 2005), which is based on inhibition of thyroidal iodine uptake in
825 adults, is also protective of concerns regarding neurodevelopmental effects of perchlorate. This
826 question is discussed in the Conclusion.

827 The current BBDR model that was relied upon for the USEPA (2017) draft approach is an extension of
828 previous models that have been validated and published in the peer-reviewed literature (Clewell et al.
829 2007; Merrill et al. 2003; Lumen et al. 2013). Similar values for key parameters have been
830 successfully used across the previous models, yet changes were made in the current model or new
831 parameters added (e.g. VCHNG, HCGreg, pTSH, KmNiS), often with little or no evidence or
832 justification provided to support these revisions in the USEPA (2017) documentation. Additional
833 support for these changes will be needed to provide validation of the current revisions to the BBDR
834 model and to provide confidence in the predictions of changes in fT4 made by the model.

835 Certainly, confidence in the BBDR model predictions is undermined by the model's inability to simulate
836 the results from the Steinmaus et al. (2016) study. In Appendix B of USEPA (2017), a comparison of
837 the predicted changes in both fT4 and TSH from the BBDR model were compared to the results
838 reported by Steinmaus et al. (2016) (reproduced in Figure 6). The Steinmaus et al. (2016) study was
839 conducted to evaluate the potential for perchlorate exposure to impact thyroid hormone levels in
840 pregnant women in San Diego. This comparison clearly highlights the differences between the model
841 predictions and those from a published study. The baseline BBDR simulations with normal iodine
842 intake (170 µg/day) demonstrate no change in fT4, which is consistent with other studies in which no
843 impact on fT4 has been observed at doses up to 7 µg/kg/day (Greer et al. 2002; Braverman et al.
844 2006). The BBDR model underpredicted changes in fT4, even in the scenario with low dietary iodine
845 intake (75 µg/day), when compared to the changes reported by Steinmaus et al. (2016). This
846 discrepancy calls into question the ability of the model to predict changes in fT4 associated with

847 perchlorate exposure. In particular, the proposed MCLG approach depends on model predictions of
848 small changes in fT4 as low as approximately 1% (Table 6) being associated with unit changes in
849 neurodevelopmental endpoints. Predictions of this precision would require a level of model precision
850 that has not been demonstrated by comparisons to existing data.

851 Many of the changes in fT4 that are predicted by the draft MCLG approach to estimate impact on the
852 population distribution of fT4 and therefore result in per unit changes in neurodevelopmental
853 outcomes are small percent changes (some as low as a 1.3-4.3% change). This would appear to
854 suggest that the extended version of the BBDR model has a capability to estimate small changes in
855 fT4 with a level of precision that is not demonstrated by any adequate validation. In fact, BBDR model
856 predictions of fT4 underpredict observed data in human studies (Tables 1 and 3) by as much as 25-
857 35%. Moreover, considering the variability of fT4 in the populations of interest, there is uncertainty as
858 to whether these slight changes could be measured clinically, considering the greater impact of iodine
859 intake on hormone levels. Considering the lack of data to support critical parameters and
860 assumptions in the model, as well as the impact of the variability of iodine intake on model
861 predictions, it seems crucial that validation of the BBDR model by comparison with observed data be
862 used to provide confidence in the predictions of the BBDR model. However, the BBDR model clearly
863 fails the only comparison that has been conducted (Figure 6), with the BBDR model predictions falling
864 outside the bounds of the statistical confidence limits estimated for the Steinmaus et al. (2016)
865 relationship between perchlorate dose and fT4. Each of the components of the BBDR model combined
866 result in compounded uncertainty in the modeling results.

867 Until additional data are available to validate current extensions of the BBDR model to the pregnant
868 woman, the Greer et al. (2002) and Braverman et al. (2006) studies provide the critical information in
869 determining concentrations of perchlorate that do not result in significant inhibition of iodide uptake
870 and, therefore, impacts on fT4. Based on recommendations from the National Academy of Sciences
871 (2005), points of departure provided by these studies used in combination with uncertainty factors
872 were considered to be protective of sensitive subpopulations, this approach has previously been relied
873 upon to support guidelines for perchlorate in drinking water under the Safe Drinking Water Act (USEPA
874 2008), and has also been used more recently by JECFA (2011) and EFSA (2014) in their regulation of
875 perchlorate.

CONCLUSIONS

We applaud the USEPA for the application of a BBDR model in their draft MCLG approaches, as these models integrate the available science for a compound of interest. However, while the hormone component of the model is a scientific improvement in terms of incorporating the available biology, there is a lack of data to provide critical validation in multiple steps of the proposed approach and to support several assumptions/parameters within the BBDR model. In particular, while no major structural defects in the USEPA (2017) BBDR model were identified, there are a number of uncertainties in the model parameterization that call into question its use for predicting very small changes in clinical hormone values, such as a 1% change in fT4 (Tables 4-6) While the model prediction for 1% change in fT4 (0.3-0.4 µg/kg/day) would yield a POD lower than the USEPA (2005) RfD, that level of precision is a not supported by the comparison of the model predictions with available data. Nonetheless, the consistency of the model-predicted PODs based on the epidemiological endpoints (Table 6), and the relationship of these results with previous risk assessments based on biologically sound precursors (iodide inhibition in thyroid), indicate that the interim health standard would be sufficiently protective against the developmental neurological endpoints of concern, as illustrated in Figure 7, which compares the point of departure from the USEPA (2005) IRIS assessment with the PoDs calculated by the BBDR model in the USEPA (2017) report (Table 6). The USEPA (2005) RfD (red bar) is protective for all of the endpoints from epidemiological studies and is consistent with a change in population fT4 levels of less than 5%.

Beginning with the initial risk characterization for perchlorate (USEPA 2002), the fundamental underpinning of the agency's risk assessment approach has been the use of an obligatory precursor as a conservative basis for protecting against downstream health effects. As elaborated in the original documentation (USEPA 2003), the effects of perchlorate are mediated by the inhibition of thyroidal iodine uptake by perchlorate. Unless perchlorate concentrations in the blood are sufficient to disrupt iodine uptake, there is no plausible basis for suggesting an effect of perchlorate on thyroid hormone homeostasis or subsequent events leading to developmental or (in the rat) carcinogenic effects. The recent studies suggesting a relationship between perchlorate exposure and decreased fT4 do not impeach this causal relationship. Therefore, until the significant uncertainties in the current BBDR

model and draft MCLG approaches can be addressed, USEPA should continue to rely on the RfD approach based on inhibition of thyroidal iodine uptake (USEPA (2005), as recommended by the National Academy of Sciences (2005) for any further regulatory action. The USEPA (2005) RfD includes an intraspecies uncertainty factor of 10 "to protect the most sensitive population, the fetuses of pregnant women who might have hypothyroidism or iodide deficiency." None of the predictions of the BBDR model suggest that this uncertainty factor is inadequate.

FUNDING

This work was supported by the American Water Works Association (AWWA), an international, nonprofit, scientific and educational society dedicated to providing total water solutions assuring the effective management of water. Founded in 1881, the Association is the largest organization of water supply professionals in the world. No employee or representative of AWWA participated in the preparation of this article, or influenced its contents or interpretations, which are exclusively those of the authors.

1135 for isolated hypothyroxinemia in pregnant and nonpregnant women of childbearing age in China. The
1136 Journal of Clinical Endocrinology and Metabolism, 100(4): 1594-1601.

1137 Zhang X, Yao B, Li C, Mao J, Wang W, Xie X, Teng X, Han C, Zhou W, Li C, Xu B, Bi L, Meng T, Du J,
1138 Zhang S, Gao Z, Yang L, Fan C, Teng W, Shan Z. 2016. Reference intervals of thyroid function during
1139 pregnancy: Self-sequential longitudinal study versus cross-sectional study. Thyroid, 26(12): 1786-
1140 1793 (As cited in USEPA 2017).

1141 Figure 1. Mode-of-action model for perchlorate toxicity proposed by the USEPA (2002).
1142 Inhibition of iodide uptake in the thyroid by perchlorate is an obligatory precursor for all
1143 downstream cancer and noncancer endpoints, including neurodevelopment.

1144 Figure 2: Structure of the Early Pregnancy BBDR (USEPA 2017)

1145 Figure 3: Variation in free T4 (fT4 in early pregnancy (as reported in USEPA 2017))

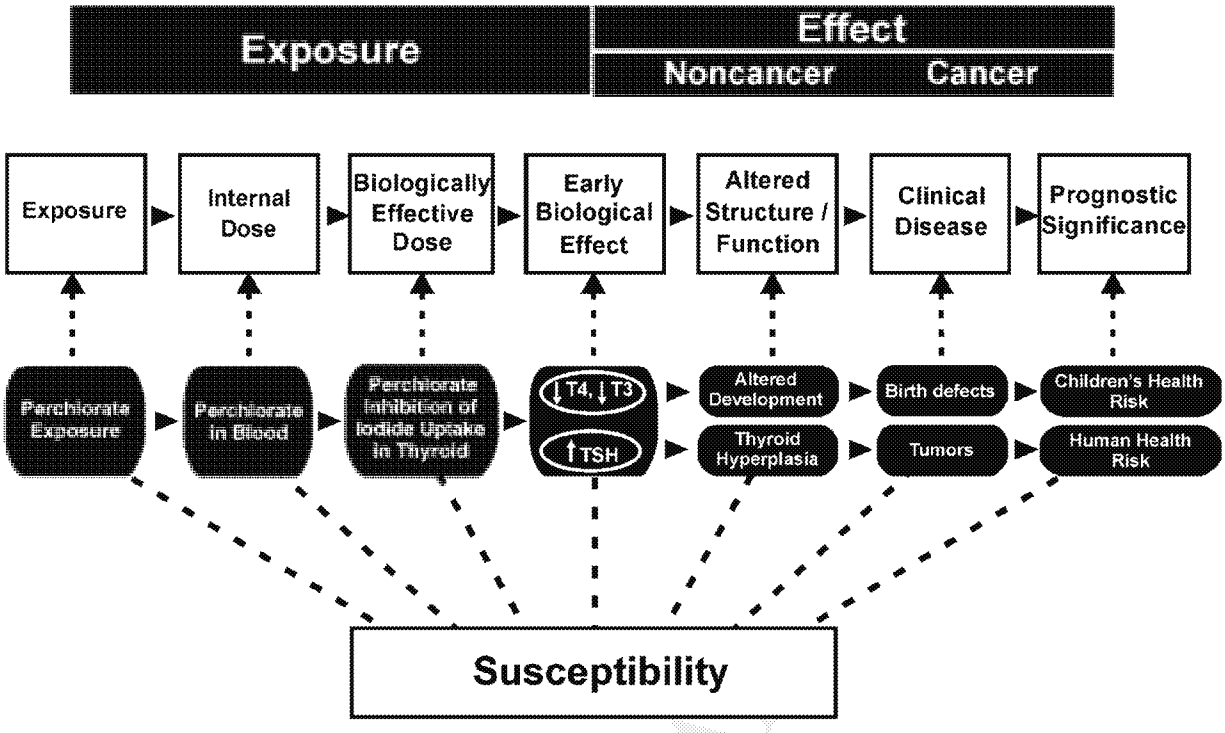
1146 Figure 4, Comparison of parameters controlling hCG-dependent changes in thyroidal uptake
1147 (VCHNG, green) and thyroid hormone production rate (HCGREG, purple) in the BBDR model as
1148 a function of gestational age. Despite the fact that both parameters are dependent upon hCG
1149 levels, the predicted trends across gestation are not consistent.

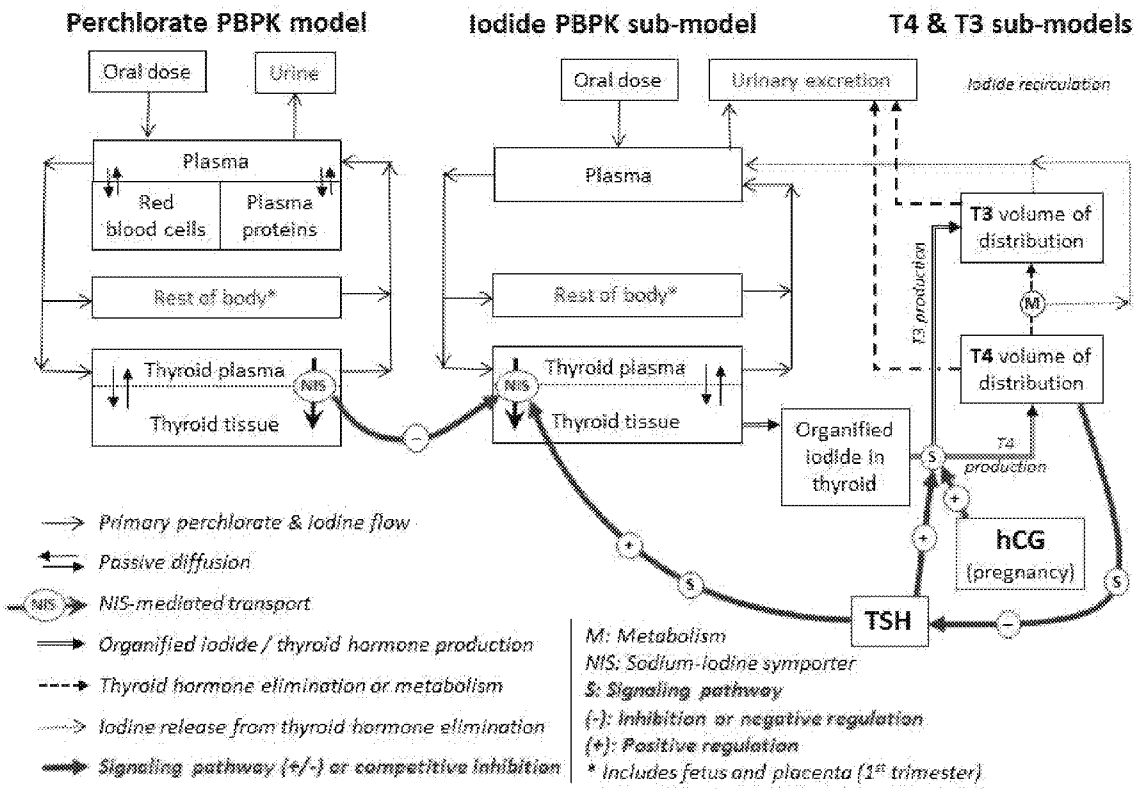
1150 Figure 5. Panel a: Model predictions for free T4 (fT4) in non-pregnant women as a function of
1151 iodine intake compared to data from NHANES 2007-2012 (USEPA 2017). Panel b: Underlying
1152 NHANES data without model predictions. Note the lack of evidence for any correlation
1153 between iodine intake and fT4 in the NHANES data in the range from 20 to 90 µg/d, in
1154 contrast to model predictions.

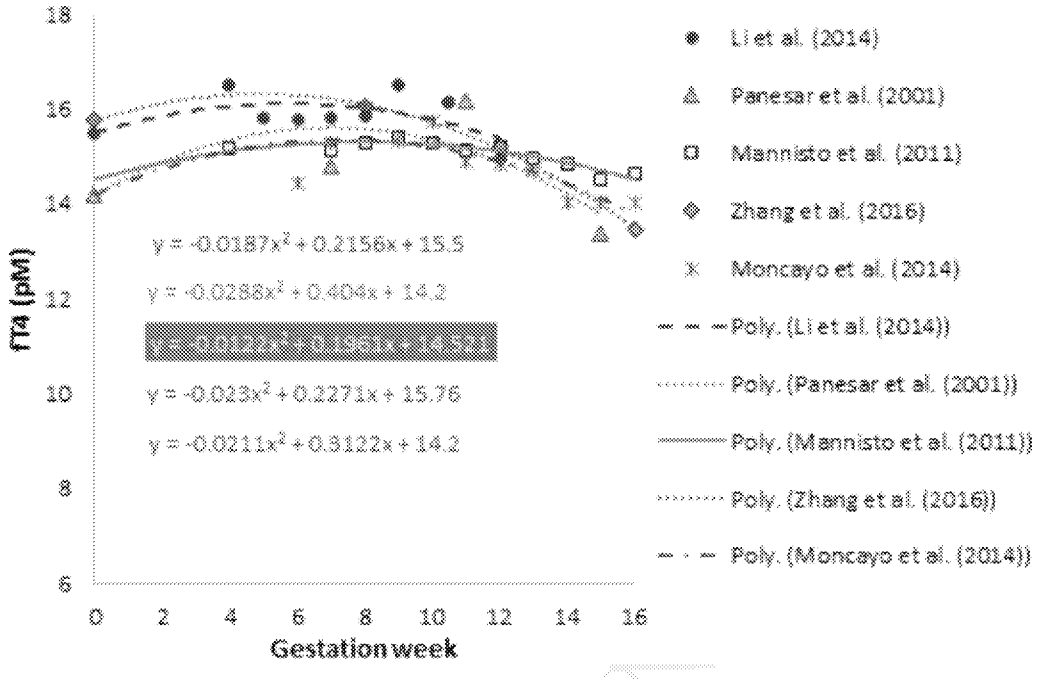
1155 Figure 6. Comparison of BBDR model predicted free T4 (fT4) changes as a function of
1156 perchlorate dose with data from Steinmaus et al. (2016). Reproduced from USEPA (2017).
1157 Blue boxes and diamonds represent the BBDR model predictions for median (170 µg/d) and
1158 low (90 µg/d) iodine intake populations (GW 13-16); red +'s represent the central estimate
1159 from the analysis of the Steinmaus et al. (2016) study and the red x's represent the upper
1160 and lower confidence limits for that estimate.

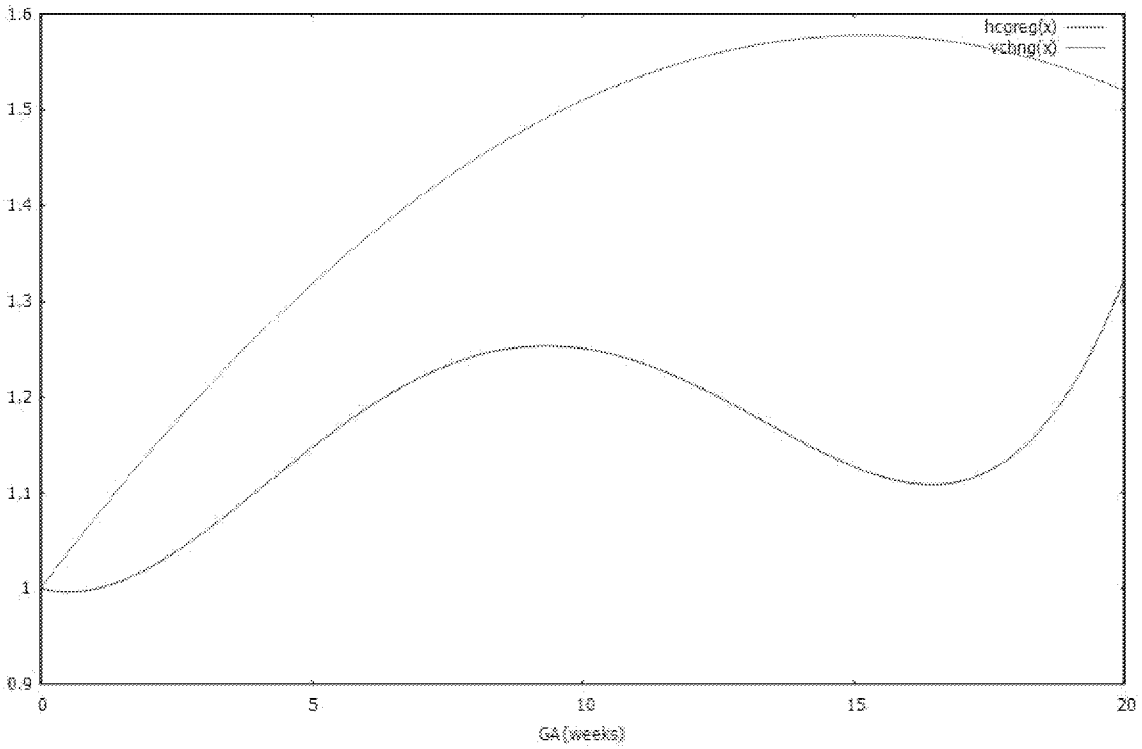
1161 Figure 7. Comparison of PoDs calculated using the USEPA (2017) BBDR model-based PoDs
1162 (blue and green bars) with the USEPA (2005) RfD (red bar).

1163

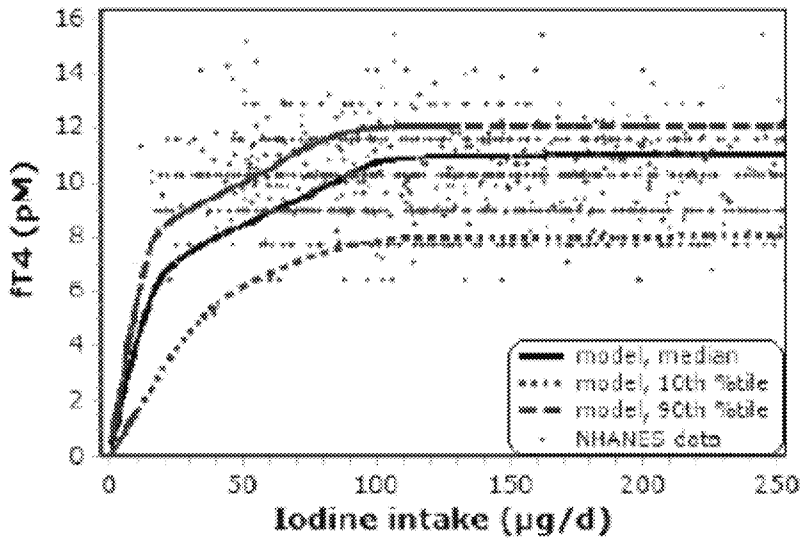




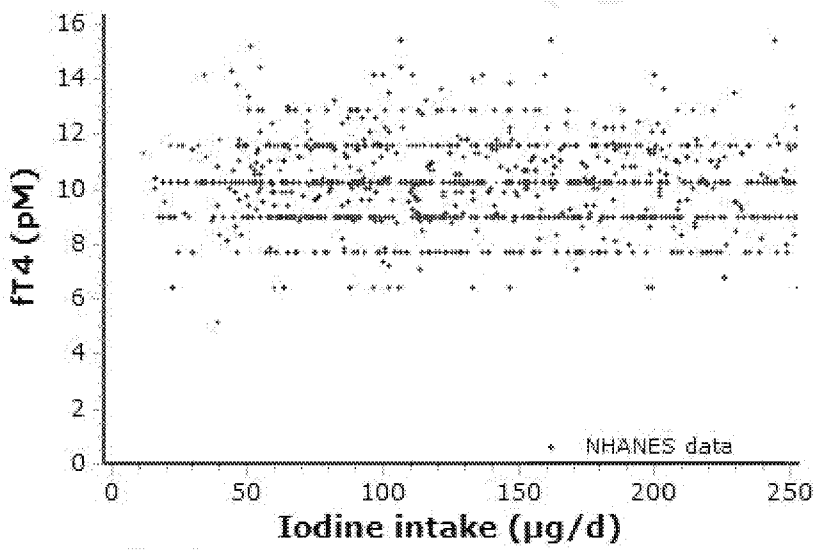


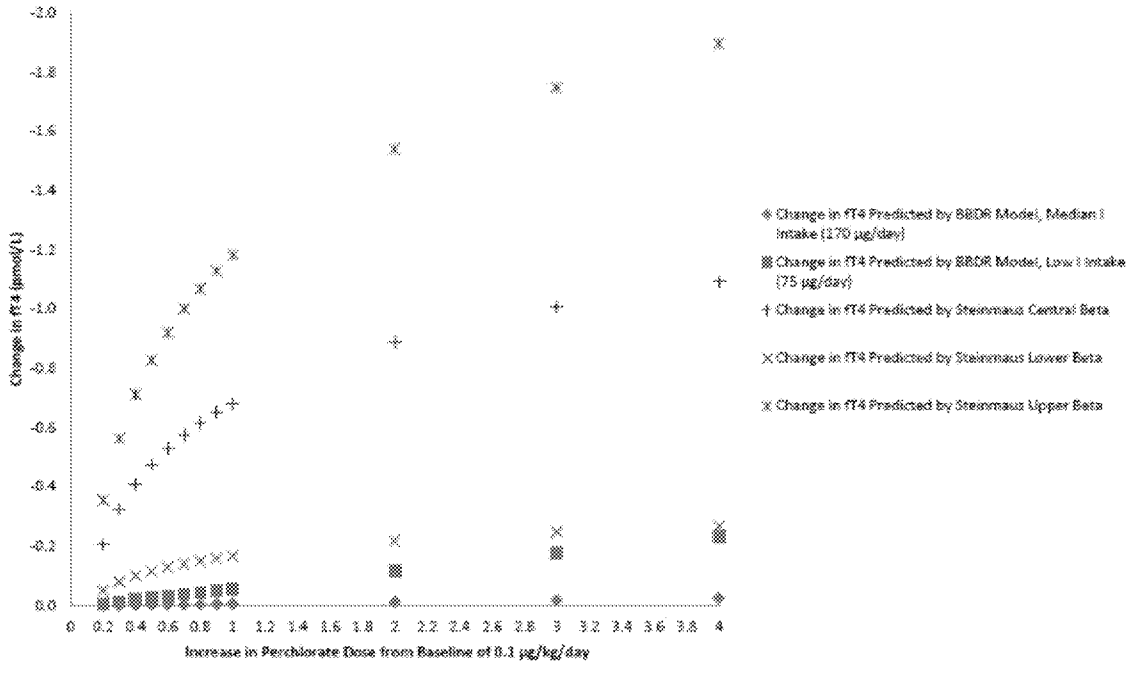


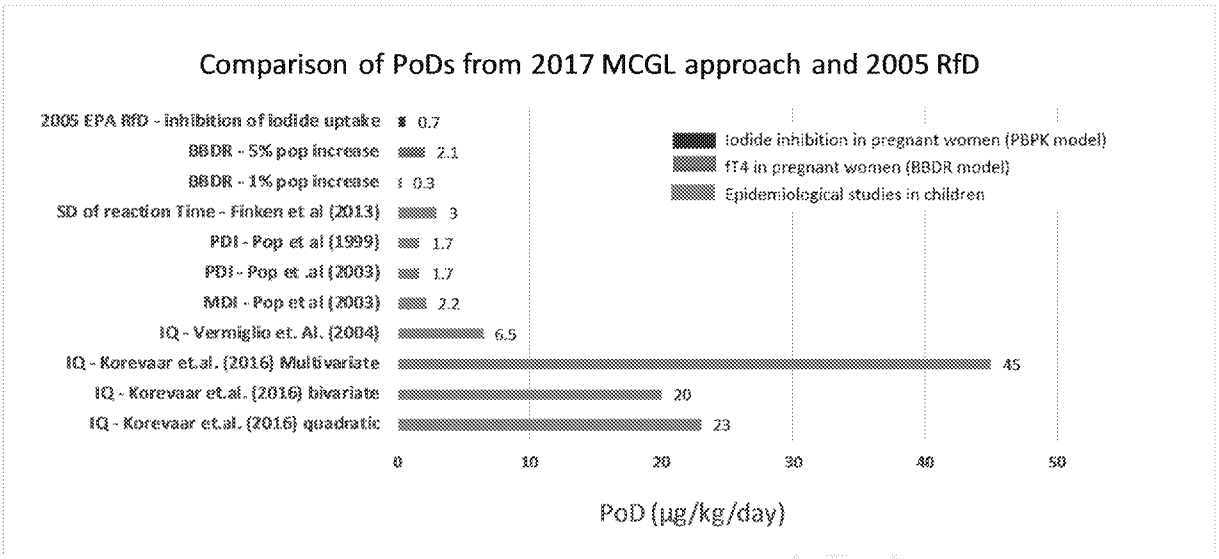
a.



b.







Highlights (maximum 125 characters, including spaces)

- The USEPA (2017) BBDR model plausibly describes perchlorate effects on thyroid hormone regulation during early pregnancy.
- The model is a valuable tool for investigating the effects of perchlorate on thyroid function during early gestation.
- BBDR modeling results indicate that the current USEPA RfD, based on adult effects, is also protective for fetal effects.
- However, current model uncertainties dictate against its use to replace the existing RfD for perchlorate.

Jennifer and Yu-Ting:
Attached for your review and comment are the transmittal memos we are preparing to facilitate Inter Agency Review of the propose perchlorate drinking water standard. We will be preparing the "blue folder"package to facilitate getting these documents to the Office of Policy for transmission to OMB for review. Please note that we have been informed that OGC concurrence requires senior level approval now and we do not expect to receive that concurrence today. Also a reminder that the Action memo is a draft at this stage of the process to identify the information we intend to highlight for the Administrator when it is transmitted for signature after OMB concludes Inter Agency Review.

Hi Sam, not sure if you're in today,

A couple more questions on perchlorate: was there a workgroup and if so, which offices were/are involved, and was the FAR (final agency review waived)?

Thanks!

Subject: Request for review - Draft Perchlorate Rule Proposal

Preliminary draft for internal EPA review

Hi,

Attached for your review is the Draft Perchlorate Rule Proposal (Preamble and Regulatory Text). As discussed previously we are asking that you provide your questions and or comments on the draft document to me by

COB 2/15/2019. In order to keep with the consent decree deadline, we need to complete this step of the process within two weeks, if there are any issues that require technical discussions please let me know so that we can arrange any necessary working meeting.

I will follow-up with another email later today that contains the draft version of the technical support documents that were used as the basis for the Perchlorate proposal. Since those are very lengthy documents we are not requesting that you submit input and/or comments on those within the two- week time frame.

Please let me know if you have any questions.

Thanks
Sam

Betsy, in prep for our meeting with Jennifer and Deborah, see the excerpt below from p. 7 of the Response to Peer Review Comments on the Draft Human Health Toxicity Values for Perfluorobutane Sulfonic Acid (CASRN 375-73-5) and Related Compound Potassium Perfluorobutane Sulfonate (CASRN 29420-49-3)

"Some peer reviewers identified one topic specifically pertaining to uncertainty in interspecies extrapolation (i.e., suggested an increase in UF_A). This reviewer opinion was based on limited human toxicokinetic data in sensitive subpopulations (e.g., pregnancy, children, neonates) and lack of information to quantify relative cross-species sensitivity in thyroid hormone toxicodynamics. The reviewers also provided minor comments primarily regarding textual clarifications in Chapter 6, including:

- Need for additional clarifying language on the physiology and function of thyroid hormones during pregnancy and further description of the clinical condition "hypothyroxinemia";"

This is the point of focus for our conversation with Jennifer.

Subject: PFBS assessment

Betsy – you may already be doing this but I wanted to make sure we are connected to ORD as they respond to their peer review comment: Need for additional clarifying language on the physiology and function of thyroid hormones during pregnancy and further description of the clinical condition "hypothyroxinemia". I'm reviewing the perchlorate response to comment document now and just want to make sure we are being consistent.

Thanks
Jennifer

Lisa,
Greg and I talked about perchlorate this morning. When we spoke on the 17th the agreement was that Greg would provide suggestions for clarity or things to cut and any comments on the draft and provide those to you by the 24th. Greg provided those comments (attached) on the 22nd. Greg informed me that he received a new draft title HESD for perchlorate from Sam asking for comment by mid next week. Looking at this draft it's clear that his previous comments were not considered. Were his comments provided to Abt?

Ex. 5 Deliberative Process (DP)

I don't feel like it is a good use of Greg's time to keep reviewing and making the same comments on the document.

I suggest that we reconvene and try to figure out the best way OST can support you all while making the best use of Greg's time.

Jamie

Subject: Draft Health Effects Document

Hi Greg,

Here is the draft document that Abt prepared based on our technical direction. Let me know if you have any comments, questions or edits that you want to provide so that the document can be modified as the final version is developed. I will appreciate if you can provide any feedback by mid next week, if possible.

Thank You
Sam

> Thanks for your questions at yesterday's briefing on perchlorate, particularly regarding EPA's analysis linking thyroid hormone level changes to IQ decrements. As we discussed, the origin of this analysis was the recommendation of the Science Advisory Board. The SAB stated "The agency should incorporate the appropriate studies related to ingestion of perchlorate, pharmacokinetics of perchlorate, the effects (dynamics) of perchlorate, and dose-response relationships from all the available literature. In developing the pharmacodynamic aspect of this model, the EPA should take advantage of available data on potential adverse health effects due to thyroid hormone perturbations, regardless of the cause of those perturbations, to document and support parameters used in the model. Accordingly, the SAB concludes that these two streams of information — biology of iodide deficiency and perchlorate inhibition of iodide uptake — are complementary and sufficient for the EPA to consider specific life stage factors in deriving an MCLG for perchlorate."
> See https://yosemite.epa.gov/sab/sabproduct.nsf/02ad90b136fc21ef85256eba00436459/d3bb75d4297ca4698525794300522ace!OpenDocument&TableRow=2.3#2 for more information.

Also, you asked about the subsequent peer reviews of the work done to implement the SAB's recommendations. As discussed, we performed these peer reviews in accordance with the Agency's guidance on Contractor Lead Highly Influential Scientific Assessments, which provides the public with opportunities to comment on both the peer reviewers and the draft report. Several of the peer reviewers for the contractor lead peer reviews were also members of the SAB panel. The first peer review focused on the BBDR model's ability to predict thyroid hormone changes associated with perchlorate exposure and the second peer review focused upon the changes made to the BBDR model and the evaluation of epidemiologic studies evaluating the relationship between thyroid changes and neurodevelopmental impacts. We sought input from Federal partners on the peer review charges and they provided comments on the draft reports in the public docket.

The Peer review docket including the peer review reports and the public input can be found at https://www.regulations.gov/docket?D=EPA-HQ-OW-2016-0439.

Also attached for your information is the current version of the scientific analysis that responds to the most recent peer review comments. Please let us know if you have any further questions or concerns that you would like to discuss.

Good afternoon Crystal,
OGWDW received one manuscript for review this week. The manuscript reports the results from the screening of ToxCast phase2 chemicals to identify inhibitors of iodide uptake. The study looks at a variety of chemicals including PFAS and uses sodium perchlorate as a reference chemical. I have forwarded the manuscript to TAB and SRRB inquiring interest in reviewing for policy and/or factual error.

Attached is the manuscript and its supplemental documents and below are some details about the review process. Please let me know if you have any questions or concerns. Hope you have a nice weekend!

Sincerely,
Nicole Tucker

Title: High-Throughput Screening and Chemotype-Enrichment Analysis of ToxCast Phase II Chemicals Evaluated for Human Sodium-Iodide Symporter (NIS) Inhibition
Author(s): Jun Wang, Daniel Hallinger, Ashley Murr, Angela Buckalew, Ryan Lougee, Ann Richard, Susan Laws, and Tammy Stoker
Purpose of study: This study reports the results from the screening of ToxCast ph2 chemicals to identify inhibitors of iodide uptake.
Received from: Mary Reiley
OGWDW Reviewer(s): Requested policy reviews from TAB and SRRB; reviewers pending
Review comments requested by: September 27,2018
Comments to be submitted to: OST-Mary Reiley

List of Exhibits

1. Introduction and Overview

Background

The U.S. Environmental Protection Agency (EPA or The Agency) is required by the Safe Drinking Water Act (SDWA), as amended in 1996, to publish a list of contaminants (Drinking Water Contaminant Candidate List, or CCL) that are known or anticipated to occur in public water systems, and which may require regulation under the SDWA. The CCL 2 was published in a Federal Register Notice (FR Notice) on February 24, 2005 (70 FR 9071). The Agency is also required to make Regulatory Determinations on at least five of the CCL contaminants following publication. EPA published preliminary regulatory determinations for 11 of 51 total contaminants from CCL 2 on May 1, 2007 (72 FR 24016). In the 2007 notice, perchlorate was not part of the list of 11 contaminants, however, the Agency asked for new information and data related to perchlorate. Subsequently, EPA made a final regulatory determination not to regulate the 11 of the contaminants identified in the May 1, 2007 *Federal Register* notice. Responses to public comment regarding these 11 contaminants were answered as part of the final regulatory determination process and posted to www.regulations.gov (refer to document ID EPA-HQ-OW-2007-0068-0178).

The Agency deferred responding to comments on perchlorate, and issued a separate preliminary determination not to regulate perchlorate on October 17, 2008 (73 FR 66895), followed by an additional public comment period. In a third *Federal Register* notice, issued on August 19, 2009 (74 FR 41883), EPA requested new information and data via public comment. The purpose of issuing the notice was to obtain comments on additional approaches to analyzing data related to EPA's regulatory determination. EPA wanted to ensure consideration of all the potential options for evaluating whether there is a meaningful opportunity for human health risk reduction of perchlorate through a national primary drinking water rule.

This final comment response document presents the comments and responses for all three comment periods. Approximately 39,000 public submissions (in the form of letters, apparent mass mailing campaigns, e-mails, and/or postings to www.regulations.gov) were received by EPA. All original public submissions can be found in their respective docket locations; at www.regulations.gov, under Docket ID EPA–HQ–OW–2007–0068 for the May 2007 notice; EPA–HQ–OW–2008–0692 for the October 2008 notice; and EPA–HQ–OW–2009–0297 for the August 2009 notice.

EPA's Categorization of Public Comments and Document Organization

Within the 3 *Federal Register* notices related to perchlorate, EPA sought public comment on a number of topics, including: regulatory determination; the approach EPA used to make its determination; new data and information; and several other issues specific to the individual FR notices. To address and respond to the public comments that were received, EPA developed a list of numerically ordered topics (referred to as "EPA Comment Codes") that were likely to be addressed by commenters (typically based on the outlines of the draft FR notices). Not all of the EPA Comment Codes were addressed by commenters. The complete list of EPA Comment Codes is provided in Appendix 1, including notation for codes that did not receive comments.

To organize and track public submissions, EPA assigned a document identification (ID) number . These "document IDs" were assigned to give each public submission a unique identifier, and to tie each submission to the docket for the *Federal Register* notice it was submitted under, or to identify it

as the representative letter from an apparent mass mailing campaign (see discussion below regarding mass mailing campaigns).

Each public submission was read by EPA, and, where appropriate, was subdivided into "comment sections," or distinct issue areas, based on topical breaks within the submission. EPA grouped these comment sections (hereinafter referred to as "comments") and assigned a five digit EPA comment identification (ID) number or "comment ID." Comments that were similar in topic were then grouped together into a corresponding EPA Comment Code. Each EPA Comment Code was assigned a four digit reference number.

Apparent Mass Mailing Campaigns – Section 2

EPA received more than 37,000 public submissions from 11 apparent mass mailing campaigns. EPA read each submission and determined if it was part of a campaign. Only one representative letter (the first letter that was received) from each campaign is included in this response to comment document. The representative letters from each campaign appear in their entirety in Section 2 of this report. Each individual letter is presented in the order in which it was originally written, separated into its individual comments (*i.e.*, at topical breaking points), with each comment followed by the associated EPA response (see explanation on the next page regarding cross referencing of responses, and response to comment codes). Each comment from a campaign also appears in Section 3, under its assigned EPA Comment Code.

Comments and Responses by Comment Code – Section 3

Section 3 presents the public comments and EPA's responses. These are organized first by EPA Comment Code, (*i.e.*, the topical subsections within Section 3); then within each Comment Code, comments are organized numerically by EPA Comment ID. Readers can first find the comment code for topics they are interested in, and then find responses to specific Comment IDs for individual comments. The commenter name, organization, and document ID are also given for each comment. Any comment can be read as it appears within the commenter's original letter, e-mail, or posting by searching on the associated Document ID on www.regulations.gov (see explanation of Document IDs in the introduction to this section, "EPA's Categorization of Public Comments and Document Organization"). The Document ID can also be used to find additional information, such as tables or figures, which may be included within the context of comments or attachments in the commenter's original submission.

Cross Referencing of Responses

In many cases, several commenters addressed the same or similar issues. For these comments, EPA has cross referenced responses to avoid redundancy and to ensure consistency. Responses are cross referenced by providing the pertinent EPA Comment ID, along with the EPA Comment Code where the EPA Comment ID is located. As noted above, Section 3 is organized first by EPA Comment Code (the subsections within the chapter), then numerically by EPA Comment ID.

Response to Comment Code

Many comments received by EPA addressed similar topics, and were thus grouped under the same EPA Comment Code. In several of these cases, the same response was appropriate for multiple comments, and EPA developed a "Response to Comment Code" which appears at the beginning of each EPA Comment Code section. Responses to individual comments may point reader to the appropriate Response to Comment Code.

Who Submitted Comments

Because EPA received approximately 39,000 public submissions it is not practical to list all commenters and the topics they commented on. However, in reviewing commenter submissions and profiles, EPA binned commenters into 12 categories to provide a broad characterization of interested stakeholders. Exhibit 1, below, lists commenter category, and the number of comments received within each category.

Exhibit 1: Public Submissions by Category Type

Category Type	Number of Public Submissions
Academia / Professional Societies (including: university departments, professors (even if writing on their own behalf))	10
Consultants	19
Drinking Water Organizations	19
Drinking Water Systems	7
Environmental Groups	44
Federal Government	4
Individual Manufacturers/Companies	2
Industry Groups	14
Local Government	6
States	31
Worker & Public Health Groups	9
Private Citizen and Anonymous Commenters	Approximately 38,817

1. Original documents can be found in the docket at http://www.regulations.gov, under Docket EPA–HQ–OW–2007–0068 for the May 2007 FR; EPA–HQ–OW–2008–0692 for the October 2008 FR; and EPA–HQ–OW–2009–0297 for the August 2009 FR.
2. A complete list of the EPA Comment Codes and their descriptions can be found in Appendix 1.

2. Apparent Mass Mailing Campaigns

Apparent Mass Mailing #1 - Physicians for Social Responsibility

EPA Document ID: EPA-HQ-OW-2008-0692-0081
EPA Comment ID: 19687
EPA Comment Code: 6120

Comment: This is a Public Comment Regarding EPA's refusal to regulate Perchlorate under the Safe Water Drinking Act (Docket ID EPA-HQ-OW-2008-0692): Perchlorate is a chemical in rocket fuel that has been linked to thyroid problems in pregnant women, newborns and young children. Not regulating this harmful chemical in our drinking water is unacceptable. Perchlorate is found in drinking water in 35 states, and according to the EPA's own data, 16 million Americans are at risk of being exposed to this dangerous chemical.

Response: See response to comment code 6120.

EPA Document ID: EPA-HQ-OW-2008-0692-0081
EPA Comment ID: 19688
EPA Comment Code: 5300

Comment: Setting a standard for perchlorate will absolutely present 'a meaningful opportunity for health risk reduction.' I urge you to do so in accordance with the Safe Drinking Water Act and protect Americans' health.

Response: See response to comment code 5300.

Apparent Mass Mailing #2 - Physicians for Social Responsibility

EPA Document ID: EPA-HQ-OW-2008-0692-0100
EPA Comment ID: 19689
EPA Comment Code: 6120

Comment: The Environmental Protection Agency (EPA), supposedly protecting us against harmful chemicals in our air, water and food, has formally refused to set a drinking- water standard for perchlorate, a chemical in rocket fuel that has been linked to thyroid problems in pregnant women, newborns and young children.

Response: See response to comment code 6120.

EPA Document ID: EPA-HQ-OW-2008-0692-0100
EPA Comment ID: 19690

EPA Comment Code: 5220

Comment: The maximum safe level for perchlorate in drinking water is now 15 times higher than what the EPA declared safe in 2002. Under this new standard, more than 16 million Americans are exposed to unsafe levels of perchlorate in their drinking water, and independent analysis shows anywhere from 20 to 40 million Americans at risk. Perchlorate has been found in the drinking water in 35 states in the U.S.

Response: See response to comment 19873 under comment code 5220.

EPA Document ID: EPA-HQ-OW-2008-0692-0100
EPA Comment ID: 19691
EPA Comment Code: 6120

Comment: The Senate Environment and Public Works Committee has endorsed legislation requiring the EPA to set a federal standard for perchlorate and to monitor levels of the chemical in tap water. Please regulate perchlorate in our drinking water: Your current decision is harmful to public health.

Response: See response to comment code 6120.

Apparent Mass Mailing #3 Group Unidentified

EPA Document ID: EPA-HQ-OW-2008-0692-0561
EPA Comment ID: 19964
EPA Comment Code: 1300

Comment: Docket Identification (ID) Number: EPA-HQ-OW-2008-0692 Preliminary Regulatory Determination on Perchlorate Re: Request for extension of comment period I am writing to express my concern regarding the EPA's failure to regulate perchlorate, as well as the proposed reference level, which fails to protect - and will adversely affect -- the health and development of hundreds of thousands, perhaps millions of American children. EPA has spent a number of years researching perchlorate and developing its conclusions - which are considered highly controversial and complex. They require, therefore, the time for measured and throughful public response. We cannot afford to have this decision rushed through, in the last days of the current administration, and leaving those communities that face the greatest risk without enough time to comment. It takes time for public and community groups to evaluate EPA's findings, review the ever-changing scientific literature, and prepare comments. I therefore request that the EPA extend the 30-day comment period on its October 10, 2008 Preliminary Regulatory Determination on Perchlorate to 90 days.

Response: See the response to comment code 1300. EPA plans to initiate the process of proposing a national primary drinking water regulation for perchlorate (see response to comment code 6120).

Apparent Mass Mailing #4 - Natural Resources Defense Council

EPA Document ID: EPA-HQ-OW-2008-0692-0687
EPA Comment ID: 20016
EPA Comment Code: 6120

Comment: Docket # EPA-HQ-OW-2008-0692 Environmental Protection Agency Mailcode: 2822T, 1200 Pennsylvania Ave., NW Washington, 20460 Dear Administrator Johnson and EPA staff, I urge you to set a drinking water standard for perchlorate that will protect pregnant women and babies nationwide. Perchlorate poses a risk for pregnant women, newborns and young children by interfering with thyroid hormone, which is critical for optimal development of the brain and nervous system. Perchlorate is found in drinking water in at least 26 states, and 20-40 million people could be exposed to this chemical. Several states have set drinking water standards or guidelines for this chemical, but these standards vary widely, so it is critical for the EPA to set a national standard that is based on the best available science and that will protect public health. The EPA's own staff scientists have determined that your decision not to regulate perchlorate places some infants and young children above safe levels of exposure. The EPA's current draft scientific analysis should undergo independent scientific peer review and should be used as the basis for the regulation.

Response:
The Agency believes that further review by the National Research Council would unnecessarily delay regulatory decision making for perchlorate. Therefore, EPA is not, at present, planning to request additional NRC review of issues related to perchlorate. Instead, EPA issued a notice in August of 2009 seeking comments on a broad range of alternative approaches to the interpretation of the scientific data relevant to a regulatory determination for perchlorate in drinking water.

EPA has determined to regulate perchlorate in drinking water. See response to comment code 6120.

EPA Document ID: EPA-HQ-OW-2008-0692-0687
EPA Comment ID: 20017
EPA Comment Code: 5300

Comment: All Americans deserve healthy and clean drinking water. The EPA should not finalize this decision until the scientific review is complete and should make decisions that are consistent with the agency's own scientists. Contrary to your claims, protecting the health of young children is indeed a "meaningful opportunity for health risk reduction."

Response: See response to comment code 5300.

EPA Document ID: EPA-HQ-OW-2008-0692-0687
EPA Comment ID: 20018
EPA Comment Code: 6120

Comment: Again, I urge you to reverse your decision and to set a national drinking water standard for perchlorate.

Response: See response to comment code 6120.

Apparent Mass Mailing #5 - Clean Water Fund/Clean Water Action

EPA Document ID: EPA-HQ-OW-2008-0692-0689
EPA Comment ID: 20019
EPA Comment Code: 6120

Comment: I urge the U.S. Environmental Protection Agency to reverse its preliminary determination on setting a regulation for perchlorate in drinking water. * perchlorate contamination is a nationwide problem and has health impacts at lower levels than previously thought; * a national primary drinking water regulation would provide a meaningful opportunity to protect public health. Additional Facts * Perchlorate is a harmful chemical used in rocket fuel, flares, and explosives. * Perchlorate, even in small amounts, can impair the thyroid gland, which controls growth, development and metabolism. * Developing fetuses, infants and children with thyroid impairment may suffer mental retardation, loss of hearing and speech or deficits in motor skills. * EPA agrees that perchlorate has been found in 395 sites in 37 states, including 153 public water systems serving over 20 million people. Some estimates are even higher.

Response: See response to comment code 6120.

Apparent Mass Mailing #6 - Earth Justice

EPA Document ID: EPA-HQ-OW-2008-0692-0972
EPA Comment ID: 20884
EPA Comment Code: 6120

Comment: Administrator Stephen L. Johnson 1101A EPA Headquarters 1200 Pennsylvania Avenue, NW, Ariel Rios Building Washington, DC 20460 Subject: Protect Our Drinking Water From Perchlorate Contamination Dear Administrator Johnson, I am writing to urge you reverse EPA's preliminary regulatory determination and set a protective drinking water standard for perchlorate as required by the Safe Drinking Water Act. Perchlorate contamination in our food and water supplies is too widespread, and its toxic effects too well known, for continued inaction on this problem.

Response: See response to comment code 6120.

EPA Document ID: EPA-HQ-OW-2008-0692-0972
EPA Comment ID: 20885
EPA Comment Code: 5240

Comment: Many experts disagree with your assessment that drinking water with 15 parts per billion of perchlorate is safe and acceptable. Scientists from the California Environmental Protection

Agency and the Massachusetts Department of Environmental Protection have set stricter standards to will ensure that the most vulnerable populations -- pregnant women, infants, and small children -- are protected from the adverse impacts of perchlorate.

Response: See response to comment code 5220.

EPA Document ID: EPA-HQ-OW-2008-0692-0972
EPA Comment ID: 20886
EPA Comment Code: 4000

Comment: EPA's analysis fails to consider that the combination of food and drinking water exposure to perchlorate in the U.S. population exceeds the reference dose set by EPA. Nor does it incorporate the more protective methodology behind the recent state regulatory actions. These flaws must be remedied for the sake of the millions of U.S. families exposed to dangerous levels of perchlorate contamination.

Response: EPA considers the combination of food and drinking water through the relative source contribution (RSC). The RSC is the percentage of the reference dose remaining for drinking water after other sources of exposure to perchlorate have been considered (e.g., food). See the August 2009 Federal Register notice (41887) for a detailed discussion of RSC derivation.

Regarding the comment about incorporating methodologies behind recent state regulatory actions, States use different methodologies or assumptions to derive their own standard based on their unique exposure scenarios. EPA has used the best available peer reviewed science in making this regulatory determination.

Apparent Mass Mailing #7 – Group Unidentified

EPA Document ID: EPA-HQ-OW-2008-0692-1518
EPA Comment ID: 20705
EPA Comment Code: 6120

Comment: I understand the dangers of perchlorate and ask you to keep the testing requirement intact for our public drinking water supplies. Removal of the testing requirement would eliminate detection of perchlorate in the case of accidental or intentional contamination of drinking water supplies, such as the Tewksbury Massachusetts contamination in 2004.

Response: See response to comment code 6120.

Apparent Mass Mailing #8 - Food and Water Watch

EPA Document ID: EPA-HQ-OW-2008-0692-1805
EPA Comment ID: 20883

EPA Comment Code: 6120

Comment: Dear Administrator Johnson, I am writing to urge you to reconsider EPA's preliminary determination not to regulate perchlorate in drinking water. Perchlorate has been found in the drinking water supply of 35 states and the District of Columbia. Widespread human exposure to perchlorate was confirmed by the Center for Disease Control's NHANES study, which found that 100 percent of the 2,820 randomly selected study participants had detectable levels of perchlorate in their urine. The widespread exposure of the population to some level of perchlorate raises serious health concerns. Perchlorate can inhibit the thyroid gland's iodine uptake, potentially leading to hypothyroidism. Severe hypothyroidism during pregnancy can lead to abnormal fetal cognitive development, and even mild hypothyroidism during pregnancy is associated with subtle cognitive defects in children. Thus, perchlorate could alter fetal brain development, having lifelong cognitive effects for those affected. EPA's failure to regulate perchlorate in drinking water places consumers - especially children and pregnant women - at risk. In response to this misguided determination, EPA's own Children's Health Protection Advisory Committee has drafted a letter expressing its concern with EPA's decision not to regulate perchlorate. Members of the committee claim that EPA rushed a decision on perchlorate without taking time to consider all the latest peer-reviewed studies. Given the vital importance of fetal central nervous development not only for long-term health and development of children, but also for the viability of fetuses, why would EPA rush to a decision? Unfortunately, the only conclusion we can draw is that EPA has issued this determination to avoid strapping the Department of Defense with costs to clean up near military bases, missile testing sites and chemical plants. While millions of consumers' health is jeopardized, it seems the budget concerns of the Pentagon or White House are driving EPA's decision. This determination is clearly another instance of a regulatory agency shirking its responsibility to protect the American public. Instead of fulfilling its obligations under the SDWA, EPA has once again folded to pressure.

Response: See response to comment code 6120.

Apparent Mass Mailing #9 - Group Unidentified

EPA Comment Code: 6120

Comment: Water Docket, EPA, Mailcode 2822T 1200 Pennsylvania Ave., NW Washington, DC 20460 To Whom It May Concern: I urge you to reverse your decision and set a federal limit for perchlorate in drinking water. Perchlorate is a nationwide problem and has health impacts at lower levels than previously thought. Please protect public health, especially infants and children, by regulating perchlorate.

Response: Please see the response to comment code 6120.

Apparent Mass Mailing #10 - Group Unidentified

EPA Document ID: EPA–HQ–OW–2009–0297-0039
EPA Comment ID: 28365
EPA Comment Code: 6120

Comment: I urge the U.S. Environmental Protection Agency to move forward with a drinking water standard of no higher than 1 part per billion for perchlorate. perchlorate contamination is a nationwide problem and has health impacts at lower levels than previously thought; protecting infants and children is critical. a national primary drinking water regulation would provide a meaningful opportunity to protect public health.

Response: See response to comment code 6120.

Apparent Mass Mailing #11 - Food and Water Watch

EPA Document ID: EPA–HQ–OW–2009–0297-0526
EPA Comment ID: 28614
EPA Comment Code: 6120

Comment: Administrator Jackson USEPA Headquarters Ariel Rios Building 1200 Pennsylvania Avenue, N. W. Washington, DC 20460 September 18, 2009 Dear Administrator Jackson, I am writing, on behalf of Food and Water Watch, to urge you to make a national primary drinking water rule for perchlorate. Perchlorate has been found in the drinking water supply of 35 states and the District of Columbia. Widespread human exposure to perchlorate was confirmed by the Center for Disease Control's NHANES study, which found that 100 percent of the 2,820 randomly selected study participants had detectable levels of perchlorate in their urine. And according to your request for comment notice, dated August 5, 2009, the number of people served by water contaminated with high levels of perchlorate ranges between 53.4 and 16.8 million people.

Response: See response to comment code 6120.

EPA Document ID: EPA–HQ–OW–2009–0297-0526
EPA Comment ID: 28615
EPA Comment Code: 2150

Comment: Your decision to not request additional NRC review of issues relating to perchlorate is ill advised. Additional NRC research may better elucidate the health effect and exposure risk we presently face. Moreover, NRC research may provide better guidance in making a final regulatory determination, especially in determining the best health reference level (HRL).

Response: Please see the response to comment ID 28822 under comment code 2150.

EPA Document ID: EPA–HQ–OW–2009–0297-0526
EPA Comment ID: 28616
EPA Comment Code: 5225

Comment: As suggested by previous commenter's, I believe that the Agency's proposed HRL, of 15 micrograms/Liter, is too high. The alternative HRLs presented in Table 2 of your request for comment notice, dated August 5, 2009, do not use the most appropriate data. The data in Table 2 uses mean ingestion rates from the CSFII. The CSFII is already several years out of date.

Response: Regarding the Agency's proposed HRL of 15 ug/L being too high, see response to comment code 5220. Regarding use of CSFII data, EPA believes that it is the best peer reviewed science that is available.

EPA Document ID: EPA–HQ–OW–2009–0297-0526
EPA Comment ID: 28617
EPA Comment Code: 3170

Comment: You also request comment on how the Agency should account for variation of perchlorate levels over time in public water systems. This is simple: the Agency should act with extreme precaution.

Response: See response to comment code 6120.

EPA Document ID: EPA–HQ–OW–2009–0297-0526
EPA Comment ID: 28618
EPA Comment Code: 6120

Comment: The widespread exposure of the population to some level of perchlorate raises serious health concerns. Perchlorate can inhibit the thyroid glands iodine uptake, potentially leading to hypothyroidism. Severe hypothyroidism during pregnancy can lead to abnormal fetal cognitive development, and even mild hypothyroidism during pregnancy is associated with subtle cognitive defects in children. Thus, perchlorate could alter fetal brain development, having lifelong cognitive effects for those affected. EPA's failure to regulate perchlorate in drinking water places consumers, especially children and pregnant women, at risk. We urge the EPA to consider the regulation of perchlorate as an opportunity to protect our waterways and make our drinking water safe for all.

Response: See response to comment code 6120.

Re: Drinking Water: Perchlorate Supplemental Request for Comments, 74 Fed. Reg. 41883 (Aug. 19, 2009); Docket ID No. EPA-HQ-OW-2007-0297; RIN 2040-AF08

Dear Sir or Madam:

These comments are submitted on behalf of the American Pyrotechnics Association ("APA"), in response to the above-referenced Notice and Supplemental Request for Comments ("Notice") appearing in the Federal Register on Wednesday, August 19, 2009. We appreciate the opportunity to provide the Agency with these comments.

Interest of the APA

The APA is the principal safety and trade association of the fireworks industry representing manufacturers, importers, distributors, retailers, suppliers, and professional public display firms. The APA has over 240 member companies. Along with their subsidiaries, APA member companies are responsible for 90 percent of the fireworks manufactured, imported, distributed and displayed in the U.S.

The fireworks industry is predominately comprised of small family businesses that together, on one day each year, serve almost all of the nation and its citizens with the very special honor of celebrating this country's most patriotic of holidays, Independence Day, the Fourth of July. This is a responsibility entrusted to us by the founders themselves.

Response: No response is necessary to the information provided by the commenter.

EPA Document ID: EPA-HQ-OW-2009-0297-0522
EPA Comment ID: 28491
EPA Comment Code: 1000

Comment: Perchlorate has recently been used in fireworks because it is essential to the formula to cause the fireworks compositions to burn properly. The perchlorate formulas replaced chlorate formulas, which were less stable and highly friction sensitive, in order to provide a much safer product. The perchlorate formulas are designed so that the perchlorate is consumed during combustion. Efforts to replace perchlorate continue, but the technology for a safe, equally effective substitute is still developing.

Response: No response is necessary to the information provided by the commenter.

U.S. Environmental Protection Agency Mailcode 2822T 1200 Pennsylvania Ave., NW. Washington, DC 20460

Subject: Docket ID No. EPA-HQ-OW-0297

Reference: Drinking Water: Perchlorate Supplemental Request for Comments (Federal Register / Vol. 74, No. 159 / Wednesday, August 19, 2009 / Notices

This letter is submitted to correct and clarify comments provided by the Nevada Division of Environmental Protection (NDEP) dated September 16, 2009 in response to the referenced "Supplemental Request for Comments" noticed by the U.S. Environmental Protection Agency (EPA) in the August 19, 2009 Federal Register; Docket ID No. EPA-HQ-OW-2009-0297.

The modifications to our earlier submittal concern the description of analytical methods and detection limits associated with perchlorate data collected and reported by the Metropolitan Water District (MWD) of Southern California for the Whitsett Intake. The NDEP is providing these corrections even though these corrections do not change the NDEP's analyses or recommendations provided in our original submittal.

The necessary corrections relate to several dates and a reporting limit that were provided on page 16 of 22 within the referenced submittal. Specifically, following submittal of initial comments by the NDEP, it came to our attention that:

* A change from a reporting limit of 4 ug/L to 2 ug/L occurred early than was referenced; * A change from EPA Method 314 to EPA Method 331 occurred earlier than was referenced; * A change from EPA Method 331 to EPA Method 332 occurred earlier than was referenced; and * The MWD is being provided a 0.1 ug/L reporting limit for EPA Method 331 and EPA Method 332.

A corrected page 16 of 22 to the September 16, 2009 NDEP submittal is attached to this letter to serve as an errata replacement page to our earlier submittal. Track change mode was used to provided clarity and transparency related to this revision. Please use the provided errata to update your records. Additionally, please contact the undersigned should you wish to discuss these data further.

The NDEP appreciates this opportunity to provide the EPA with helpful information to enable the EPA to make a thoughtful and credible decision regarding whether there is a meaningful opportunity for health risk reduction to persons served by public water systems through promulgating a national drinking water rule for perchlorate.

Sincerely, Tom Porta, Deputy Administrator Nevada Division of Environmental Protection

Ms. Lisa P, Jackson Administrator U.S. Environmental Protection Agency 1200 Pennsylvania Avenue, NW Washington, DC 20460

RE: EPA-HQ-OW-2009-0297, "Drinking Water: Perchlorate - Supplemental Request for Comments," 74 FR 159:41883, 19 August 2009

Dear Ms. Jackson:

The California Space Authority (CSA) is a nonprofit corporation representing the commercial, civil, and national defense/homeland security interests of California's diverse space enterprise community. Therefore, we feel compelled to share our concern regarding the Environmental Protection Agency (EPA) request for public comments regarding data related to EPA's perchlorate regulatory determination (the Notice; U.S. EPA, 2009b).

Earlier this year, President Obama issued a broad directive that would guarantee scientific integrity in all federal policy making. We strongly support this policy standard. CSA believes that additional approaches proposed by EPA which support a possible regulatory determination are consistent with this directive.

There is a substantial body of scientific evidence related to the health risks associated with perchlorate. Five decades of scientific investigation, including a landmark National Academy of Sciences (NAS) review, result in a clear and consistent conclusion: low levels of perchlorate are not dangerous to public health.

CSA respectfully requests that the EPA support sound public policy which protects human health and is based on solid science standards.

Sincerely, Janice Dunn Deputy Director

Response: Please see the response to comment code 6120.

Water Docket Environmental Protection Agency Mailcode 2822T 1200 Pennsylvania Avenue, NW Washington, DC 20460

RE: Docket No. EPA-HQ-OW-2009-0297, "Drinking Water: Perchlorate - Supplemental Request for Comments," 74 FR 159:41883, 19 August 2009

Dear Sir/Madam:

The Grocery Manufacturers Association (GMA) represents the world's leading food, beverage and consumer products companies. The Association promotes sound public policy, champions initiatives that increase productivity and growth and helps to protect the safety and security of the food supply through scientific excellence. The GMA board of directors is comprised of chief executive officers from the Association's member companies. The $2.1 trillion food, beverage and consumer packaged goods industry employs 14 million workers, and contributes over $1 trillion in added value to the nation's economy.

GMA appreciates this opportunity to provide comments on the above referenced public notice regarding alternative approaches to the interpretation of the scientific data relevant to a regulatory determination for perchlorate in drinking water.

Response: No response is necessary to the information provided by the commenter.

Commenter Name: Diane VanDe Hei
Commenter Organization: Association of Metropolitan Water Agencies (AMWA)
EPA Document ID: EPA-HQ-OW-2009-0297-0494
EPA Comment ID: 28826
EPA Comment Code: 1000

Comment: AMWA's comments are presented in two parts. The first part focuses on several areas where AMWA requests clarification or makes recommendations including: EPA's alternative HRL analysis, review of this analysis and the PBPK model by the National Academies National Research Council, EPA's population estimates, the Inspector General (IG) report, the significance of the reference dose (RfD) being set at a no observed effect level (NOEL) rather than a no observed adverse effect level (NOAEL), and the science surrounding perchlorate. The second part of the

letter provides responses to three issues where EPA specifically requested comment in the Federal Register (FR) notice.

Response: No response is necessary to the information provided by the commenter.

Commenter Name: Michael Girard
Commenter Organization: Perchlorate Study Group
EPA Document ID: EPA-HQ-OW-2008-0692-1855
EPA Comment ID: 29080
EPA Comment Code: 1000

Comment: Is perchlorate known to occur or is there a substantial likelihood that perchlorate occurs at a frequency and at a level of public health concern in public water systems?

Perchlorate is not known or likely to occur in public water systems with high enough frequency nor does it occur at levels of public health concern. The NHANES studies and breast milk biomonitoring studies, notwithstanding their limitations, reveal that the US population is not exposed to levels of perchlorate that could cause an adverse effect, even when all exposure sources - in food and water - are considered.

In the NHANES results, Americans 6 years and older had a 50th percentile dose of perchlorate at the time of sampling equivalent to 2.2 ppb in drinking water. (Blount, 2006) This dose is less than 10 percent of the conservative NOEL level that is the basis of EPA's RfD and 7,000 times lower than the NOAEL. Less than 0.004% of the population has the potential for exposure to perchlorate above the RfD. (Blount, 2006) By all standard regulatory benchmarks EPA uses to determine acceptable incremental potential population risk from drinking water exposure, total perchlorate exposure has not required regulation. If total exposure does not present a meaningful risk for regulatory purposes, it follows that the risk from exposure to perchlorate in drinking water only is even smaller.

The sole effect of setting a drinking water standard would be to reduce this already insignificant fraction. Rarely does EPA have both toxicology and exposure measures of such high quality. This evidence shows that drinking water is not a significant source of perchlorate for the population.

The nationally-representative Unregulated Contaminant Monitoring Rule 1 results show that perchlorate does not occur frequently or at levels of public health concern in public water systems. The process for collecting data on unregulated contaminants in large and small water systems has been well established and relied upon by EPA for past Contaminant Candidate List (CCL) regulatory determinations. The UCMR is the most complete source of information on contaminant occurrence in the nation's drinking water sources. The use of UCMR sampling data for regulatory determinations has been well established.

Response: EPA has determined that perchlorate occurs or there is a substantial likelihood that perchlorate will occur with a frequency and at levels of health concern in public water systems. Therefore, EPA has determined to regulate perchlorate in drinking water. See response to comment code 6120.

EPA disagrees with the interpretation of the NHANES studies and breast milk monitoring revealing that the US population is not exposed to levels of perchlorate that could cause an adverse effect. The NHANES studies did not measure exposure in infants and children under the age of 6. In light of the discussion presented in the final regulatory determination notice and the information available at this time, EPA believes that a NPDWR for perchlorate could reduce perchlorate exposures to levels below the potential alternative HRLs.

EPA disagrees with the statement that the UCMR 1 results show that perchlorate does not occur frequently or at levels of public health concern in public water systems. EPA believes that the UCMR 1 is the best available data on the frequency and level of perchlorate occurrence in public water systems nationally. UCMR 1 indicated that 5.1 to 16.6 million people are served by PWSs, for which we have data, that have detected perchlorate at levels above the potential health levels.

Commenter Name: James Taft
Commenter Organization: Association of State Drinking Water Administrators (ASDWA)
EPA Document ID: EPA-HQ-OW-2007-0068-0169
EPA Comment ID: 20285
EPA Comment Code: 1100

Comment: States are also very interested in the contaminants for which a decision has not yet been proposed but where EPA shared information in the notice on the status of its analysis of these chemicals. Contaminants in this category include MTBE and perchlorate. ASDWA appreciates the fact that EPA chose to share extensive information on these contaminants in the notice, since some of these contaminants are "hot" topics in many states. Even if regulatory decisions are not yet made, states need to know the current status to help them deal with public water systems where these contaminants have been found. ASDWA encourages EPA to continue to provide information on the status of their regulatory deliberations especially for contaminants like MTBE and perchlorate where there has been significant public and legislative interest. ASDWA and individual states are ready to assist and provide input to EPA's decision making at any time. We offer the following specific observations about perchlorate, metolachlor, and MTBE .

Response: See response to comment ID 20264 under comment code 7100.

EPA Comment ID: 20287
EPA Comment Code: 1100

Comment: National regulations covering a contaminant that may be a very localized problem need to be considered very carefully. They must be supported by scientific data. If further information is needed on the sources of human exposure, states urge the Agency to consider such additional documentation before a regulatory determination is made. If analysis of additional data does support regulation, states do not believe there is adequate justification for establishing a new national drinking water standard. Under such circumstances, its primary impact would be to add more water quality monitoring without necessarily enhancing public health protection. If an MCL is eventually developed based on somewhat localized occurrence patterns, we would encourage the Agency to consider requiring targeted monitoring, based on preliminary initial rounds of monitoring, rather than uniform monitoring across the board.

Response: EPA intends to develop monitoring requirements for perchlorate as part of a proposed National Primary Drinking Water Regulation.

Commenter Organization:
EPA Document ID: EPA-HQ-OW-2008-0692-1625
EPA Comment ID: 20564
EPA Comment Code: 1100

Comment: Please include perchlorate on the EPA's Contaminant Candidate List. I am concerned with the potential health risks to all living things from exposure to perchlorate, especially in drinking water. By leaving this contaminant on the EPA's Contaminant Candidate List, it will be given attention needed to control it's use and disposal properly and safely to prevent significant future pollution problems to the environment. As a licensed professional engineer with the State of Connecticut, I urge you to reverse the EPA's decision to remove this dangerous contaminant from the CCL and place it back on the CCL as it should be there. Please help keep this dangerous chemical out of our drinking water.

Response: EPA included perchlorate on the first, second, and third Contaminant Candidate Lists that were published in the Federal Register on March 2, 1998 (63 FR 10273), February 24, 2005 (70 FR 9071), and October 8, 2009 (74 FR 51850), respectively. EPA has decided to regulate perchlorate in drinking water. See response to comment code 6120.

Commenter Name: Ron Curry
Commenter Organization: New Mexico Environment Department
EPA Document ID: EPA-HQ-OW-2008-0692-1796
EPA Comment ID: 20940
EPA Comment Code: 1100

Comment: Furthermore, section 1412(b)(3)(A) of the SDWA requires that the EPA Administrator, when making a decision based on science, shall use "the best available peer-reviewed science and supporting studies conducted in accordance with sound and objective scientific practices."[FN27: 42 U.S.C. [section] 300g-1(b)(3)(A) (Westlaw 2008).] However, according to EPA's Science Advisory Board (SAB), EPA's preliminary determination not to regulate perchlorate "relies on the use of a dosimetric model which is now undergoing letter peer review."[FN28: Letter from Dr. Deborah L. Swackhammer, Chair, EPA Science Advisory Board, and Dr. Joan Rose, Chair, EPA Science Advisory Board, Drinking Water Committee, to EPA Administrator Stephen L. Johnson, at 1 (Nov. 5,2008).] Yet EPA plans to make a final determination whether to regulate perchlorate by December 2008.[FN29: 73 Fed. Reg. at 60281.] Consequently, the SAB has expressed concern that the soundness of the dosimetric model "will not be publicly vetted."[FN30: Letter from Dr. Swackhammer & Dr. Rose, at 1.] The SAB stresses the importance of such peer review: "The quality of the scientific foundation for EPA's decisions depends on peer review, which brings a variety of scientific perspectives to bear on critical components of EPA's decisions. Where science assessments have been conducted with the benefit of external scrutiny, the end products have been better able to support the policy making process."[FN31: Id. at 2.7] It is critical, therefore, that EPA make the determination whether to regulate perchlorate with the benefit of fully peer-reviewed, and publicly- scrutinized scientific analysis. Failure of EPA to do so would be arbitrary and capricious and not in accordance with the requirements of the SDWA.

Thank you for your consideration of these comments.

Ron Curry Cabinet Secretary

cc:Governor Bill Richardson Sarah Cottrell, Office of the Governor Attorney General Gary King Stephen R. Farris, Office of the Attorney General

Response: Administrator Stephen Johnson replied to the SAB on January 9, 2009. The letter is available in EPA's docket ID No. EPA-HQ-OW-2009-0297 for this notice. EPA agrees with the commenter that it is critical that EPA make the determination whether to regulate perchlorate with the benefit of fully peer-reviewed scientific analysis, which is available to the public. This comment was received prior to EPA's peer-review process for the PBPK (dosimetric) model, which has now been completed. EPA has made this determination based on a consideration of the best available peer reviewed science and data collected in accordance with accepted methods related to perchlorate occurrence in drinking water, the presence of perchlorate in foods, and the potential health effects of exposure to perchlorate.

EPA Comment ID: 20983
EPA Comment Code: 1100

Comment: BACKGROUND

In 1974, Congress enacted the federal Safe Drinking Water Act (SDWA) to protect the public health from contaminated drinking water supplies by regulating public drinking water systems. The SDWA was amended in 1986 and 1994, and requires EPA, inter alia, to publish national primary drinking water regulations, which must include both non-enforceable, health-based Maximum Contaminant Level Goals (MCLGs) and enforceable Maximum Contaminant Levels (MCLs).[FN7: 42 U.S.C. §300g-1(a)(1).] The MCLG must be set "at the level at which no known or anticipated adverse effects on the health of persons occur and which allows for an adequate margin of safety."[FN8: 42 U.S.C. §300g-1(b)(4)(A).] In contrast, the MCL, the maximum level of a regulated contaminant that any particular covered public water system may deliver to any user, must be set "as close to the maximum contaminant level goal as is feasible."[FN9: 42 U.S.C. §300g-1(b)(4) (B).] SDWA requires EPA to set a national primary drinking water standard when it determines for a contaminant that:

(i) the contaminant may have an adverse effect on the health of persons; (ii) the contaminant is known to occur or there is a substantial likelihood that the contaminant will occur in public water systems with a frequency and at levels of public health concern; and (iii) in the sole judgment of the Administrator, regulation of such contaminant presents a meaningful opportunity for health risk reduction for persons served by public water systems.[FN10: 42 U.S.C. §300g-1(b) (1)(A).]

SDWA also requires EPA to establish a "contaminant candidate list" (CCL) identifying a list of contaminants, not yet regulated by the Agency, which are known or anticipated to occur in drinking water and which may require regulation.[FN11: 42 U.S.C. §300g-1(b)(1)(B).] Every five years, EPA must determine whether or not to regulate five of the contaminants that appear on the CCL.[FN12: Id.] In March, 1998, EPA's first CCL included perchlorate, but the Agency did not choose to make any determination about whether to regulate the contaminant. In February, 2005, EPA announced

its second CCL, CCL2, on which perchlorate appeared again. As a result of its status as a candidate contaminant, EPA subsequently announced this preliminary determination on perchlorate.

Response: No response necessary to the information provided by the commenter.

Comment: November 26, 2008

Mr. Stephen L. Johnson Administrator U.S. Environmental Protection Agency 1200 Pennsylvania Avenue, N.W. Washington D.C. 20460

Dear Administrator Johnson:

In follow-up to EPA's October 10, 2008 preliminary regulatory determination for perchlorate in drinking water, the National Drinking Water Advisory Council (NDWAC) would like to again convey to EPA the necessity for more thorough health effects research to support Safe Drinking Water Act (SDWA) related regulations. While NDWAC members do not have a consensus position to relay on the perchlorate decision itself, the members fully support the need for a strong, scientifically valid basis upon which to make such decisions.

On June 24, 2008, the NDWAC expressed to you our recommendation for a holistic drinking water research plan that includes the needed health effects research for Contaminant Candidate List (CCL) contaminants. The NDWAC strongly supports the CCL process and recommends that EPA consider a refocus of research priorities in order to ensure sound health effects data are available in a timely fashion to better inform future CCL decision-making processes. The availability of this type of information will become increasingly important as issues such as pharmaceuticals and personal care products in drinking water continue to be of concern to the public.

Under the provisions of the SDWA the nation looks to EPA to set drinking water standards which are protective of the public's health. When adequate health effects research information is lacking, important regulatory determinations can be controversial and potentially misguided. Lacking EPA leadership on standard setting, states can be pressed into making independent regulatory determinations. In the case of perchlorate, at least two different drinking water standards have already been set by California and Massachusetts. In addition, Congress may also be compelled to by-pass the CCL process when inadequate health effects data results in controversial regulatory determinations.

Thank you for your consideration of this key recommendation on research needs. If you have any questions, please contact Veronica Blette, Designated Federal Officer for the NDWAC, at (202) 564-4094.

Sincerely, Gregg Grunenfelder Chair National Drinking Water Advisory Council

cc: Benjamin H. Grumbles, Assistant Administrator for Water George Gray, Assistant Administrator for Research and Development Cynthia C. Dougherty, Director,Office of Ground Water and Drinking Water Ephraim King, Director, Office of Science and Technology Kevin Teichman, Deputy Assistant Administrator for Research and Development EPA Docket ID No. EPA-HQ-OW-2008-0692

Response: EPA agrees that thorough health effects research can improve regulatory decision-making. We will continue to work with the NDWAC and other advisory groups to identify research needs for future decisions.

Commenter Name: Michael Girard
Commenter Organization: Perchlorate Study Group
EPA Document ID: EPA-HQ-OW-2008-0692-1855
EPA Comment ID: 21103
EPA Comment Code: 1100

Comment: Finally, should a final determination be made not to establish a NPDWR for perchlorate, EPA should also make clear that its final determination also removes perchlorate from the CCL3 list. Based on EPA's careful consideration of the scientific evidence, it has fully evaluated perchlorate and met its requirements under the law. Continued consideration of perchlorate would siphon resources away from the long list of other substances and microbes on the CCL3.

Comment: REGULATORY BACKGROUND

In 1974, Congress enacted the federal Safe Drinking Water Act (SDWA) to protect the public health from contaminated drinking water supplies by regulating public drinking water systems. The SDWA was amended in 1986 and 1994, and requires EPA, inter alia, to publish national primary drinking water regulations, which must include both non-enforceable, health-based Maximum Contaminant Level Goals (MCLGs) and enforceable Maximum Contaminant Levels (MCLs).[FN7: 42 U.S.C. [Sec] 300g-1(a)(1).] The MCLG must be set "at the level at which no known or anticipated adverse effects on the health of persons occur and which allows for an adequate margin of safety."[FN8: 42 U.S.C. [Sec]300g-1(b)(4)(A).] In contrast, the MCL, the maximum level of a regulated contaminant that any particular covered public water system may deliver to any user, must be set "as close to the maximum contaminant level goal as is feasible."[FN9: 42 U.S.C. [Sec]300g-1(b)(4)(B).] SDWA requires EPA to set a national primary drinking water standard when it determines for a contaminant that:

(i) the contaminant may have an adverse effect on the health of persons; (ii) the contaminant is known to occur or there is a substantial likelihood that the contaminant will occur in public water systems with a frequency and at levels of public health concern; and (iii) in the sole judgment of the Administrator, regulation of such contaminant presents a meaningful opportunity for health risk reduction for persons served by public water systems.[FN10: 42 U.S.C. [Sec] 300g-1(b)(1)(A).]

SDWA also requires EPA to establish a "contaminant candidate list" (CCL) identifying a list of contaminants, not yet regulated by the Agency, which are known or anticipated to occur in drinking water and which may require regulation.[FN11: 42 U.S.C. [Sec]300g-1(b)(1)(B).] Every five years, EPA must determine whether or not to regulate five of the contaminants that appear on the CCL.[FN12: Id.]

In March, 1998, EPA's first CCL included perchlorate, but the Agency did not choose to make any determination about whether to regulate the contaminant. In February, 2005, EPA announced its second CCL, CCL2, on which perchlorate appeared again. As a result of its status as a candidate contaminant, EPA subsequently announced its preliminary determination not to regulate perchlorate in October, 2008.

Comment: Consideration For Future Regulations

The current regulatory framework in place in the US puts the burden on the government to show that a chemical is unsafe and must be regulated. This is a very slow process, which takes many years or even decades and often is done only after the presence of the specific chemical and its impacts have become well known. More importantly, the current process also lacks any incentive for chemical manufacturers to support source water protection, or to consider or disclose negative impacts of their products on human health and the natural environment and control the contaminants at generation points, which often would be much more economical than treating them at downstream water plants.

The issue is becoming a critical one as new analytical methods can detect ever- increasing contaminants of emerging concern at parts per trillion and below, and as potential treatment to remove them could significantly add to the financial burden of water utilities, their energy needs and greenhouse gas emissions.

These concerns can be resolved effectively and economically by a regulatory paradigm shift to put the lead responsibility where it belongs, i.e. on the generators of the contaminants. While it is not possible to address perchlorate in this way, in light of the new administration's reanalysis of the science of perchlorate, AMWA encourages this administration to also consider taking another look at how we can protect watersheds and drinking water quality by addressing preventable problems caused by the generators of chemicals and man-made sources of pollution.

EPA Comment Code: 1300 Length of the comment period following the October 2008 FR Notice

Response to Comment Code 1300: A number of commenters requested that EPA extend the 30 day comment period for the Agency's preliminary regulatory determination for perchlorate (73 FR 60262, October 10, 2008). In response to these comments, EPA extended the comment period until November 28, 2008, which provided commenters with 49 days to prepare comments. EPA received comment letters from over 37,000 individuals/ organizations on the October 2008 Federal Register Notice.

Docket identification (ID): EPA-HQ-OW-2008-00692 Preliminary Regulatory Determination on Perchlorate

Re: Request for extension of comment period.

The October 10, 2008 Federal; Register notice announcing EPA.s preliminary regulatory determination on perchlorate opened the public comment period for 30 days, with comments due by November 10, 2008. Given the importance of the science on perchlorate and the exposure data, the Natural Resources Defense Council (NRDC) respectfully requests a 60-day extension of the public comment period to January 10, 2008 (that is, 90 days from the October 10, 2008 notice).

Response: See the response to comment code 1300.

Commenter Name: Jennifer Sass, PhD
Commenter Organization: Natural Resources Defense Council (NRDC)
EPA Document ID: EPA-HQ-OW-2008-0692-0322
EPA Comment ID: 19813
EPA Comment Code: 1300

Comment: Council (NRDC) respectfully requests a 60-day extension of the public comment period to January 10, 2008 (that is, 90 days from the October 10, 2008 notice).

EPA.s preliminary regulatory determination not to set a regulatory standard for perchlorate in drinking water could put 20 - 40 million people at risk for perchlorate toxicity, including infants, toddlers and pregnant women. A proposal with such far-reaching public health implications deserves careful and thorough comments with adequate time to review and respond to EPA.s analysis.

Part of EPA.s preliminary determination relies on perchlorate monitoring data from the Unregulated Contaminant Monitoring Rule. The large amount of occurrence data collected over five years from almost 4000 public water systems will require additional time for NRDC and other stakeholders to review and assess, especially in light of the importance EPA placed on these data in the preliminary determinations.

NRDC plans to submit public comments on this proposed determination, and a thoughtful and detailed technical response will require more than the 30 days that has been allotted by EPA. We respectfully request the comment period be extended by 60 days.

Response: See response to comment code 1300.

Re: Request for extension of comment period for Docket Identification (ID): EPA- HQ-OW- 2008-0692- Preliminary Regulatory Determination on Perchlorate

Dear Mr. Burneson:

EPA announced it's preliminary regulatory determination on perchlorate in the Federal Register notice dated October 10, 2008 and opened a public comment period for 30 days, with comments due by November 10, 2008. Given the far- reaching public health implications ofEPA's determination, the Environmental Working Group (EWG) plans to thoroughly review EPA's document and submit comments. The document that EPA has produced is 80 pages long and highly technical and EWG respectfully requests that the comment period be extended by 60 days, so comments will be due 90 days from the October 10, 2008 notice.

Response: See response to comment code 1300.

Commenter Name: Anila Jacob, M.D., M.P.H.

Commenter Organization: Environmental Working Group
EPA Document ID: EPA-HQ-OW-2008-0692-0466
EPA Comment ID: 19895
EPA Comment Code: 1300

Comment: Perchlorate contamination of drinking water potentially affects 20 to 40 million US. residents and EPA's preliminary regulatory determination not to regulate perchlorate has serious health implication for these millions of people. A thorough and detailed response to EPA's determination will require EWG scientists to pore qver EPA's document line by line in order to effectively make our argument for stringent regulation of perchlorate in drinking water. As advocates for public health, EWG has a responsibility to submit the strongest document to EPA that we can and we feel that an extension of the public comment period by 60 days will allow us to do that.

Thank you for your consideration. Best regards, Anila Jacob, M.D., M.P.H. Senior Scientist Environmental Working Group

Comment: Docket Identification (ID) Number: EPA-HQ-OW-2008-0692 Preliminary Regulatory Determination on Perchlorate Re: Request for extension of comment period

I am writing to express my concern regarding the EPA's failure to regulate perchlorate, as well as the proposed reference level, which fails to protect - and will adversely affect -- the health and development of hundreds of thousands, perhaps millions of American children.

EPA has spent a number of years researching perchlorate and developing its conclusions - which are considered highly controversial and complex. They require, therefore, the time for measured and throughful public response.

We cannot afford to have this decision rushed through, in the last days of the current administration, and leaving those communities that face the greatest risk without enough time to comment.

It takes time for public and community groups to evaluate EPA's findings, review the ever-changing scientific literature, and prepare comments.

I therefore request that the EPA extend the 30-day comment period on its October 10, 2008 Preliminary Regulatory Determination on Perchlorate to 90 days.

Response: See the response to comment code 1300. EPA plans to initiate the process of proposing a national primary drinking water regulation for perchlorate (see response to comment code 6120).

Comment: Docket Identification (ID) Number: EPA-HQ-OW-2008-0692 Preliminary Regulatory Determination on Perchlorate Re: Request for extension of comment period

Americans cannot afford to have a final determination on Perchlorate's safety rushed through in light of the high scientific controversy surrounding the matter. Therefore, I request an extension of public comments from 30 days to 90 days. This action by the EPA would be appropriate and prudent given the high scientific and academic controversy over the matter. Even the mere appearance of "rushing" is in appropriate and should be dispelled by providing Americans the opportunity to fully evaluate and meaningfully comment on the EPA's proposed perchlorate determination.

The EPA has spent a number of years researching perchlorate and developing its conclusions. To now turn around and provide the American public 30 days for public comment on a complex matter is both unfair and questionable and certainly not aimed at obtaining "public comment."

Sincerely,

S. Quezada

Mr. Eric Burneson Office of Ground Water and Drinking Water Standards and Risk Management Division Environmental Protection Agency 1200 Pennsylvania Avenue, NW Washington, DC 20460 Re: Request for extension of comment period for Docket Identification (ID): EPA- HQ-OW-2008- 0692- Preliminary Regulatory Determination on Perchlorate

Dear Mr. Burneson:

On October 10, 2008, EPA published a Federal Register notice announcing the opening of a 30-day comment period on its preliminary regulatory determination on perchlorate. We have concerns regarding the proposed regulatory determination, in particular the unprecedented use of a pharmacodynamic model to justify the exceedance of the reference dose and we believe this introduces complexity into the evaluation of the standard that merits more than just 30 days for judicious scientifically-sound public comment. We therefore request that the comment period be extended by 60 days, so comments will be due 90 days from the October 10, 2008 notice, on January 10, 2009.

Thank you for considering this request.

Sincerely, Caroline Baier-Anderson, Ph.D. Health Scientist

Reg. 60262 Docket Identification (ID): EPA-HQ-OW-2008-00692

Dear Mr. Burneson: On behalf of our more than 1.2 million members, we request an extension of the public comment period for the Preliminary Regulatory Determination on Perchlorate of at least 60 days beyond the November to deadline, for a total extension of not less than qo days to January to, 2009. The proposed Preliminary Regulatory Determination on Perchlorate raises complex issues which require more time to be sufficiently reviewed. Furthermore, the Determination makes conclusions which contradict those made by several states, such as Massachusetts and New Jersey, which have reviewed the same issue and have set a drinking water standard for percblorate. The Determination raises serious implications for human health. These include the exposure to

perchlorate by millions of Americans in their food and the adverse effects of perchlorate exposure to those most at risk, including infants, toddlers, and pregnant women. Additional time will enable us to analyze and make informed comments regarding the Preliminary Determination. Please make this letter part of the comment record for the Preliminary Determination. Thank you for your attention to this request.

Sincerely,

Lyn Thorp National Campaign Coordinator Ext. 109

Paul Schwartz National Policy Coordinator Ext. 105

Comment: Water Docket Environmental Protection Agency Mailcode: 2822T 1200 Pennsylvania Ave., NW Washington, DC 20460

Docket Identification (ID) Number: EPA-HQ-OW-2008-0692 Preliminary Regulatory Determination on Perchlorate Re: Request for extension of comment period

I am writing to express my concern regarding the EPA's failure to regulate perchlorate, as well as the proposed reference level, which fails to protect - and will adversely affect -- the health and development of hundreds of thousands, perhaps millions of American children.

EPA has spent a number of years researching perchlorate and developing its conclusions - which are considered highly controversial and complex. They require, therefore, the time for measured and throughful public response.

We cannot afford to have this decision rushed through, in the last days of the current administration, and leaving those communities that face the greatest risk without enough time to comment.

It takes time for public and community groups to evaluate EPA's findings, review the ever-changing scientific literature, and prepare comments.

I therefore request that the Sincerely, EPA extend the 30-day comment period on its October 10, 2008 Preliminary Regulatory Determination on Perchlorate to 90 days.

Sincerely,

Tatjana Thomas

Response: See the response to comment code 1300. EPA plans to initiate the process of proposing a national primary drinking water regulation for perchlorate (see response to comment code 6120).

The Maryland Department of the Environment ("Department") submits the following comments on EPA's preliminary regulatory determination on perchlorate.

Request for Extension of the Public Comment Period

As a preliminary matter, the Department requests that EPA extend the public comment period. EPA's preliminary determination not to set a regulatory standard for perchlorate in drinking water has serious public health implications for the millions of people potentially exposed to perchlorate through public drinking water systems. EPA's determination was based on an analysis of highly complex data and an unprecedented application of published models with adjustments that have not undergone peer review. A thorough and thoughtful review of EPA's analysis and preliminary determination requires more than the 30 days currently allotted by EPA. The Department, therefore, requests that EPA extend the public comment period by a minimum of 60 days beyond the current November 10, 2008 deadline for submitting comments.

Response: See the response to comment code 1300.

Comment: November 13, 2008

Mr. Eric Burneson Office of Ground Water and Drinking Water Standards and Risk Management Division Environmental Protection Agency 1200 Pennsylvania Avenue, NW Washington, DC 20460

Re: Second request for extension of comment period for Preliminary Regulatory Determination on Perchlorate, Docket ID EPA-HQ-OW-2008-0692

Dear Mr. Burneson:

On October 10, 2008, EPA published a Federal Register notice announcing the opening of a 30-day comment period on its preliminary regulatory determination on perchlorate and on October 27th we submitted to the docket a letter requesting that the comment period be extended for 60 days (EPA-HQ- OW-2008-0692-0649). On November 7, EDF was notified by telephone that the comment period has been extended only 18 days, until November 28, 2008, but that the notice for this extension would not be entered into the Federal Register until Wednesday, November 12, two days after the initial deadline for comments.

We believe that this extension is inadequate, for the following reasons:

1. As noted in our previous letter, the Preliminary Regulatory Determination on Perchlorate is based on the virtually unprecedented use of a pharmacodynamic model developed by industry to justify the exceedance of the reference dose. This model and its novel application introduce significant complexity into the evaluation of the standard, which merits more than just 30 days for judicious scientifically-sound public comment.

2. Providing only an 18-day extension to this comment period is far shorter than and hence not consistent with other extensions EPA has granted. For example:

* Three extensions were made to the comment period for the "Draft List of Initial Pesticide Active Ingredients and Pesticide Inerts to be Considered for Screening under the Federal Food, Drug, and Cosmetic Act", consisting of 60 days, 45 days, and 42 days, for a total of 147 days (EPA-HQ-OPPT-2004-0109; FRL-8346-5).

* The comment period for the re-registration of Chloropicrin, Dazomet, Metam Sodium/Potassium, and Methyl Bromide was extended for 45 days (EPA-HQ- OPP-2008-0518; FRL-8380-5).

* The comment period for the "Proposed Rule for Standards of Performance for Portland Cement Plants" was also extended by 45 days (EPA-HQ-OAR-2008-0260; FRL-8703-2).

3. Since presumably you could only contact those commenters whom you knew or anticipated were planning to submit comments, the failure to post the notice of the extension in a timely manner placed any commenters not known to you at a significant disadvantage. (An incorrect docket number published in the initial notice also likely serves to further confuse and delay commenters.)

We therefore reiterate our request that the comment period be extended by at least 60 days, with comments due no earlier than 90 days from the October 10, 2008 notice, or January 10, 2009. We consider this request to be both reasonable and justified by the complexity of and importance of the decision. It is also more in line with other extensions the Agency has granted.

We request a reply at your earliest convenience.

Thank you again for your consideration.

Sincerely,

Caroline Baier-Anderson, Ph.D. Health Scientist

Response: EPA considered this request for a second extension beyond the revised November 28, 2008 extension but concluded that a further extension beyond the 49 days provided was not needed for commenters to consider the information in the 1 page Federal Register Notice and would unnecessarily delay decision making.

Commenter Name: Deborah Swackhamer

Docket Identification (ID) Number: EPA-HQ-OW-2008-0692 Preliminary Regulatory Determination on Perchlorate Re: Request for extension of comment period

Americans cannot afford to have a final determination on perchlorate's safety rushed through in light of the high scientific controversy surrounding the matter. Therefore, I request an extension of public comments from 30 days to 90 days. This extension would be appropriate and prudent given the high scientific and academic controversy over the matter. Even the mere appearance of "rushing" to a final determination is inappropriate and should be dispelled by providing Americans the opportunity to fully evaluate and meaningfully comment on the EPA's proposed action.

The EPA has spent a number of years researching perchlorate and developing its conclusions. To now, turn around and provide the American public 30 days for public comment on a complex matter is both unfair and questionable as to whether the EPA truly seeks to obtain the public's comments (to which the EPA must articulate a rational response in its final adoption of any perchlorate's final determination).

Sincerely, S. Quezada 416 Ridgeview Ave Iowa City, Iowa 52246

Re:Comments on Preliminary Regulatory Determination on Perchlorate Docket ID No. EPA-HQ-OW-2008-0692

Dear Administrator Johnson:

By this letter I am submitting the comments of the New Mexico Environment Department on the Preliminary Determination on Perchlorate that the United States Environmental Protection Agency (EPA) issued on October 3, 2008. 73 Fed. Reg. 60262 (Oct.10, 2008). Although EPA initially requested comments by November 10, 2008, the agency subsequently extended the comment period through November 28, 2008. 73 Fed. Reg. 66895 (Nov. 12, 2008). The Environment Department appreciates the opportunity to comment on this important regulatory decision, and the extension of time to submit these comments.

Response: No response necessary to the information provided by the commenter.

EPA Comment ID: 21091
EPA Comment Code: 1300

Comment: II. The EPA Should Publish its Final Determination as Soon as Possible

In the Federal Register notice, EPA has set a timeline for public comment, a final decision, and the possible decision to set a Health Advisory (HA). EPA's timeline for a final determination is wise for two principal reasons. First, the 45-day period provides ample time for the public to review EPA documents and submit comments as EPA has offered substantial opportunities for public comment on this matter. EPA previously provided a 60-day public comment period on the Contaminant Candidate List 2 (CCL) preliminary regulatory determinations for 11 chemicals issued May 1, 2007 via publication in the Federal Register as well as on its website.[FN1: 72 Fed. Reg. 24016 (2007) (published May 1, 2007).] In that publication, EPA also extended the opportunity to the public to comment on perchlorate. The PSG and other organizations commented extensively on that notice. EPA, indicating it was not issuing a determination at that time, discussed the various scientific and technical data being reviewed and considered by the agency, including the National Academy of Sciences (NAS) report, the Unregulated Contaminant Monitoring Rule 1 (UCMR) occurrence data, and options to use data to establish the relative source contribution (RSC). The agency also identified options for potential methodologies that could be employed to make a determination, including the option of using the NHANES and UCMR 1 data. EPA has selected that approach as its basis for its preliminary determination. Thus EPA has offered the public multiple opportunities for public comment, more than most substances on the CCL for which EPA has made a determination.

Response: See the response to comment code 1300.

Re: Request for extension of comment period for Docket Identification (ID) EPA- HQ-OW-2008-0692-Perchlorate Supplemental Request for Comments

Dear Mr. Burneson,

In the Federal Register on August 19, 2009, EPA published a notice seeking comments under a 30 day public comment period on "additional approaches available for analyzing data related to EPA's perchlorate regulatory determination."

The sorghum industry has been using the chemical perchlorate for many years. It is essential to producers because it aids in the dry down process and allows crops to be harvested properly without additional moisture.

Even though perchlorate is naturally occurring, EPA states in the August 19, 2009 Federal Register notice that the "additional alternatives under consideration could result in health reference levels which are much lower than the level identified in the October 2008 notice."

Since the public comments collected under this Federal register could have serious affects on sorghum producers, the National Sorghum Producers asks that EPA establish the appropriate science based methodology before proceeding with a regulatory determination. EPA has raised a number of complicated scientific issues in this Federal Register notice that will impact our

producers. On their behalf, we are requesting that the comment period be extended by 60 days to allow for a more thorough analysis of the issues raised.

Thank you for your consideration.

Sincerely, David L. Thomas

Comment: Please see the attached letter to Assistant Administrator Silva from the National Association of State Departments of Agriculture requesting a 30-day extension of the comment period in response to EPA's supplemental request for comments on perchlorate.

Attachment

September 18, 2009

The Honorable Peter S. Silva Assistant Administrator for Water U.S. Environmental Protection Agency 1200 Pennsylvania Avenue, NW Washington, DC 20460

Re: Perchlorate Supplemental Request for Comments (Docket ID No. EPA-HQ- OW-2009-0297)

Dear Assistant Administrator Silva:

The National Association of State Departments of Agriculture (NASDA) respectfully requests a 30-day extension of the public comment period for the supplemental request for comments on perchlorate so that state regulators, as well as impacted sectors of our nation's agriculture economy, have an appropriate opportunity to review the approach EPA has taken in its evaluation of perchlorate.

NASDA represents the commissioners, secretaries, and directors of the state departments of agriculture in all fifty states and four U.S. territories. NASDA'S members are responsible for a wide range of public health programs from food safety to combating the spread of disease. Moreover, as co-regulators with EPA, NASDA's members are the lead state agencies responsible for administering, implementing and enforcing the laws regulating the production, labeling, distribution, sale, use and disposal of pesticides. This broad range of responsibilities gives our members a significant basis of relevant expertise in responding to the request for comment in the August 19, 2009 Federal Register.

We are concerned that the approaches EPA described in the August 19, 2009 Federal Register are a significant departure from the traditional methods by which EPA has analyzed scientific and technical data. Previous opportunities for public comment on the traditional approaches for analyzing data related to perchlorate have allowed for comments periods of up to 60 days. In light of this, and because the approaches detailed in the August 19, 2009 Federal Register differ significantly from those used for perchlorate and other Contaminant Candidates, an additional 30 days is necessary.

Response: See response to comment code 1600.

Re: Perchlorate Supplemental Request for Comments (Docket ID No. EPA-HQ-OW-2009-0297)

Dir Sir/Madam:

The National Association of State Departments of Agriculture (NASDA) represents the commissioners, secretaries, and directors of the state departments of agriculture in all fifty states and four U.S. territories. NASDA'S members are responsible for a wide range of public health programs from food safety to combating the spread of disease. Moreover, as co-regulators with the Environmental Protection Agency (EPA), NASDA's members are the lead state agencies responsible for administering, implementing and enforcing the laws regulating the production, labeling, distribution, sale, use and disposal of pesticides.

This broad range of responsibilities gives our members a significant basis of relevant expertise in responding to EPA's August 19, 2009 request for comment on alternative approaches to interpreting data related to EPA's earlier regulatory determination for perchlorate in drinking water. The comments NASDA is submitting today are intended to supplement comments submitted on September 18, 2009 in which NASDA requested additional time to review the approaches outlined by EPA.

Response: No response necessary to the information provided by the commenter.

EPA Comment Code: 2000 Perchlorate Health Effects

Response to Comment Code 2000: EPA used the January 2005 National Research Council (NRC) study "Health Implications of Perchlorate Ingestion," a review of the state of the science regarding potential adverse health effects of perchlorate exposure and mode of action for perchlorate toxicity (NRC, 2005) in developing this regulatory determination. The NRC recommended that EPA use data from the Greer *et al.* (2002) human clinical study as the basis for deriving a reference dose for perchlorate (NRC, 2005). Although the NRC committee concluded that hypothyroidism is the first adverse effect in the continuum of effects of perchlorate exposure, NRC recommended that "the most health-protective and scientifically valid approach" was to base the perchlorate RfD on the inhibition of iodide uptake by the thyroid, which the NRC considered a non-adverse effect (NRC, 2005). The NRC recommended that EPA apply an intraspecies uncertainty factor of 10 to the no observed effect level (NOEL)[1], to account for differences in sensitivity between the healthy adults in the Greer *et al.,* (2002) study and the most sensitive population, fetuses of pregnant women who might have hypothyroidism or iodide deficiency. They viewed this as conservative and protective of health given that the NOEL is based on a non-adverse effect (iodide uptake inhibition), which precedes the adverse effect in a continuum of possible effects of perchlorate exposure. The NRC also noted that "any decrease (in thyroid hormone) is potentially more likely to have adverse effects in sensitive populations (people with thyroid disorders, pregnant women, fetuses, and infants). EPA's Integrated Risk Information System (IRIS) adopted the NRC's recommendations resulting in an RfD of 0.7 µg/kg/day (USEPA, 2005b).

Comment: I think you should regulate perchlorate in drinking water unless you know the following:

1. That perchlorate and thiocyanate don't have a synergistic effect within the thyroid by virtue of perchlorate inhibiting the conversion of thiocyanate to sulfate within the thyroid. Such an effect would increase the level of toxic sulfite in the thyroid. EPA chemist Ed Urbanski told me the EPA considered molybdenum co-factor enzymes, and perhaps subunits of those enzymes (sulfite oxidase is a subunit of nitrate reductase) to be perchlorate targets.

2. That adhesion of perchlorate to albumin and similar proteins in the blood and skin, which occurs in the blood before inhibition of the sodium iodide symporter and continues in the skin after perchlorate is cleared from the blood and thyroid, never forms a hapten that triggers an autoimmune reaction similar to iododerma and bromoderma. This seemed pertinent to Burleson's skin contact

[1] No observed effect level (NOEL) - an exposure level at which there are no statistically or biologically significant increases in the frequency or severity of any effect between the exposed population and its appropriate control.

sensitivity data in the 2002 external peer review, but there was no discussion of these traits of chaotropic salts in the EPA evaluation.

3. That perchlorate doesn't inhibit the effectiveness of defensin at its positively-charged 6-cysteine structure. Such an effect may help explain the aplastic anemia reported from medicinal doses of perchlorate by promoting infection by B-19 parvovirus. B-19 parvovirus is also associated with thyroid autoimmunity and thyroid cancer.

4. That pendrin is not the primary means of excreting perchlorate from the kidneys. If pendrin is the primary means of excreting perchlorate, then persons in a state of acidosis or low blood bicarbonate would retain perchlorate and be more vulnerable to its effects. Premature infants, infants with diarrhea, smokers, and adults with poorly managed diabetes in particular fit in this category of patient.

5. That extra-thyroidal sodium iodide symporter in the salivary glands, bronchial epithelium, gastric mucosa,and elsewhere in the body is not more sensitive to perchlorate than thyroidal sodium iodide symporter in the thyroid that is upregulated by TSH. Interference with proper function of non-thyroidal NIS may promote increased nitrosation in the gastric fluid, insufficient thiocyanate supply for myeloperoxidase, and gastrin imbalance. The function of NIS in the gastrointestinal tract was totally ignored in the EPA's decision not to regulate -- not a single GI tract specialist was consulted.

Response: EPA agrees with the commenter that the Agency should regulate perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard. EPA has considered and discusses in this Federal Register notice the results of current scientific literature on potential adverse biological effects, in the process of evaluating the adverse human health effects of perchlorate. The Agency analyzed the additional information, and EPA has determined that a national primary drinking water regulation for perchlorate would present a meaningful opportunity for health risk reduction for persons served by public water systems.

Comment: Please review your decision regarding perchlorate regulation in water. The extremely high oxidizing potential of perchlorates produces radical species in water which have been determined as causing health problems - hydroxyl radicals, oxychlorides and the potential to form tri- and bi- halomethanes. The harsh effects of even low concentrations of highly oxidizing reactive species on organic tissues has not been fully studied and evaluated, yet their typical impacts have been determined to mutate and react to damage biological life forms.

Comment: RE: Docket ID No. EPA-HQ-OW-2008-0068 Comments on the US Environmental Protection Agency's Preliminary Regulatory Determination on Perchlorate November 5, 2008

Thank you for the opportunity to comment on the USEPA Office of Water's Preliminary Regulatory Determination on Perchlorate. My comments address the relative sensitivities of the mammary and thyroid glands to the iodine-uptake- inhibiting effects of perchlorate and the implications that difference has for perchlorate's reference dose (RfD). In short, scientific evidence indicates that the thyroid gland is 10 times more sensitive to the effects of perchlorate than the mammary gland; the 10X uncertainty factor currently incorporated into the RfD is thus protective not only of pregnant women but of nursing infants as well.

EPA's current RfD for perchlorate is, of course, based on perchlorate's ability to inhibit the thyroid gland's uptake of iodide by competing for the sodium (Na+)/iodide (I?) symporter (NIS), the protein responsible for transporting iodide into the thyroid gland for the purpose of synthesizing thyroid hormones. Because iodide uptake does not constitute an adverse effect itself, its choice as the basis for the RfD is health-protective. Insufficient iodide can result ultimately in changes in thyroid hormone levels, although normally such changes are compensated for. Insufficient thyroid hormone levels can impair normal fetal growth and development. Although studies have not specifically demonstrated adverse effects in children attributable to perchlorate,(1) the adverse effects of insufficient iodide are well known.

Because the perchlorate RfD was based on a study performed using healthy adults, it incorporates a 10X uncertainty factor to protect the most sensitive population the fetuses of pregnant women who might have hypothyroidism or iodide deficiency.(1) Iodide deficiency among pregnant women in the US is apparently not uncommon.(2)

Recent concern about the adequacy of perchlorate's RfD has focused on the results of studies demonstrating the presence of perchlorate in human milk at higher concentrations than in serum,(3) potentially posing a disproportionate risk to nursing infants. Although higher concentrations of milk perchlorate have not been associated with reduced milk iodide concentrations,(3) its presence in milk has led some to suggest that an additional uncertainty factor of 10 is needed to protect nursing infants.(4) An additional uncertainty factor of 10 is unnecessary, however, because the current RfD already protects nursing infants.

The current RfD protects nursing infants because the potency of perchlorate as an iodide uptake inhibitor has been shown to be ten times weaker for the mammary gland than for the thyroid gland.(5,6) In other words, it would take ten times as much perchlorate exposure to inhibit mammary iodide uptake to the same extent as thyroid iodide uptake. There are two possible explanations for the difference: the mammary NIS is simply different and less easily inhibited compared to the thyroid NIS, or there are two mechanisms by which the mammary gland takes up iodide and the non-NIS mechanism compensates in part for the NIS when the latter is inhibited.

There is no evidence supporting or refuting the first explanation but there is evidence supporting the second.(6)

The second mechanism by which the mammary gland obtains iodide is through the pendrin-iodide transporter.(7) When thyroid iodide uptake is inhibited, serum levels increase significantly, making more iodide available to the mammary gland (or placenta) and allowing the non-NIS mammary gland processes to help protect the newborn against inhibition.(8)

Thus because the mammary gland is ten times less sensitive to iodide uptake inhibition by perchlorate compared to the thyroid gland due to the presence of an iodide uptake mechanism that is not only unaffected by perchlorate but compensates for its effects, the current perchlorate RfD of 0.7 Âµg/kg/day is adequate to protect nursing newborns and an additional uncertainty factor is not needed.

I would be happy to provide further information upon request.

Comment: Perchlorate Poses a Significant Risk to Human Health

The principle mode of action of perchlorate has been well-characterized: perchlorate blocks iodide uptake in the thyroid by the sodium (Na+)-iodide (I-) symporter (NIS), an ion channel initially identified as the mechanisms of iodide uptake in the basal membrane of thyroid follicular cells (Stanbury and Wyngaarden 1952; Wyngaarden et al. 1952), which is necessary for thyroid hormone synthesis. The selectivity of perchlorate for the sodium-iodide symporter (NIS) is as much as 30-fold greater than for iodide (Tonacchera et al. 2004) suggesting that low concentrations of perchlorate can out-compete iodide for uptake into the thyroid.

Significant inhibition of iodide uptake results in decreased production of iodine-rich thyroid hormones triiodothyronine (T3) and thyroxine (T4). Thyroid hormone production is regulated by a negative feedback system referred to as the hypothalamic-pituitary-thyroid axis. The thyroid produces T4 and T3; the pituitary gland produces thyroid stimulating hormone (TSH); and the hypothalamus produces thyrotrophic-releasing hormone (TRH). Cells in both the hypothalamus and pituitary gland respond to low levels of circulating T4 and T3; the hypothalamus stimulates the pituitary gland through TRH to produce TSH, which then prompts the thyroid to produce T4 and T3. Circulating plasma proteins can bind T4 and T3, serving as a reservoir. When thyroid production levels are low the output of TRH and TSH increase.

Response: EPA agrees that perchlorate may pose an adverse risk to human health, as discussed in more detail in the preamble announcing the final determination. Also, see response to comment code 2000.

Comment: P.O. Box 13222 Sacramento, CA95813 December 12, 2008

Dr. Melanie Marty, Chair Children's Health Protection Advisory Committee Air Toxicology and Epidemiology Branch Office of Environmental Health Hazard Assessment 1515 Clay Street Suite 1600 Oakland, CA 94612

Dr. Marty:

On behalf of the Perchlorate Study Group (PSG) I am writing in response to your November 3 letter to US EPA Administrator Steven Johnson regarding the Agency's preliminary determination on perchlorate. To be more specific, I'm writing in the hopes of addressing the various concerns you have raised and providing some additional perspective for your consideration.

First, a little about the PSG. As manufacturers and users of perchlorate, the PSG is committed to ensuring the best available science is provided in public debate and applied in the subsequent setting of regulatory standards. The member companies of the PSG include Aerojet, American Pacific (AMPAC), Alliant Techsystems (ATK), and Tronox.

By providing funding for scientific studies without interposition on the design, execution, or results for more than ten years, the PSG has worked cooperatively and effectively with the US Environmental Protection Agency (EPA) and other federal agencies, state governments, and water purveyors to:

* increase scientific and medical understanding of perchlorate's possible effects on human health; and,

* assess the level of perchlorate in drinking water that is not expected to cause adverse effects even in the most sensitive population.

We read your November 3 letter with great interest. In that letter, you raised several concerns with the scientific foundation of EPA's preliminary determination and questioned whether EPA gave sufficient consideration to the health effects of perchlorate on sensitive populations other than pregnant women and their fetuses.

As you are aware, EPA has been studying the health effects of perchlorate for more than 15 years releasing their first guidance document in 1992. Few chemicals have been the subject of such extensive research and so many peer- reviewed published studies. One of the unique scientific aspects of perchlorate is that we have a comprehensive understanding of how it affects the body. Due to its previous medical use and knowledge of the mechanism of action reduces uncertainty compared to most environmental chemicals. After several studies, draft risk assessments, guidance document revisions-- as well as an extensive and comprehensive review by the National Academy of Sciences (NAS), Agency for Toxic Substances and Disease Registry (ATSDR), and subsequent studies which have confirmed the NAS perchlorate panel's conclusions-- EPA is well positioned to issue its determination.

Response: EPA agrees that it has considered all relevant and best available science in making the final determination to regulate perchlorate. Also, see response to comment code 2000.

Comment: 2. Your letter asserts that EPA's decision does not take into account that the developing brain is sensitive to small decreases in thyroid hormone levels and that neonates have diminished stores of thyroid hormone relative to adults.

No references to support your position are provided in your letter. Thus it is difficult to assess the literature you may have used to support your statement. Nevertheless, there are some points to consider. First, thyroid hormones and pituitary hormones have normal and common temporal variability for a number of reasons (i.e., circadian rhythms, ambient temperature, etc.) Small changes in thyroid hormones are unlikely to cause long-term effects. To be adverse, changes due to chemical agents would have to be of a sustained, clinically significant magnitude over a period of time.

Second, a very small number of scientists have argued that the infant has less storage of iodine or thyroid hormone than the adult which would make the infant more vulnerable than the pregnant woman or its fetus. However, the RfD is based on no inhibition of iodide uptake, a non adverse and fully reversible effect. The half-life of perchlorate is short (approximately 8 hours) and it does not bioaccumulate. Basing an RfD that cautiously prevents the first step in the biochemical pathway would prevent any downstream event from occurring. Thus any differences between adults and children are not likely to be a factor since the first step, inhibition of IUI, is prevented. Moreover, in its assessment of perchlorate and the identification of the most sensitive population, the NAS considered all the relevant literature, including those reporting the storage and half life of thyroidal parameters. With their review, the NAS made the assessment that in pregnant women, infants and children, and people who have a low iodide intake or pre-existing thyroid dysfunction, the dose required to cause a decrease in thyroid hormone production may be lower. However, a dose that does not inhibit thyroid iodide uptake will not affect thyroid function, even in subjects with an abnormal thyroid gland or a very low iodide intake. (NAS, 2005)

Response: EPA has considered the sensitive subpopulations of newborns and infants. Please see the response to comment ID 21063 under comment code 4220 and response to comment ID 19898 under comment code 2000.

EPA Comment Code: 2000

Comment: The EPA's National Center for Environmental Assessment (NCEA) prepared draft risk assessments for perchlorate in 1998 and 2002. The proposed reference doses (RfD) were 0.0009 mg/kg-day in 1998 and 0.00003 mg/kg-day in 2002. Using EPA's conventional (or default) conversion factors, these reference doses translated to drinking water values of 32 and 1 ppb, respectively. Both reference doses proposed by EPA/NCEA were based on the results of animal studies. In 2002, EPA/NCEA interpreted these studies as showing adverse effects in the pups of rats exposed during pregnancy to a perchlorate dose as low as 0.01 mg/kg-day (U.S. EPA, 2002).

Public comments on the 2002 draft risk assessment raised serious concerns about the validity of using these animal studies for human health risk assessment (U.S. EPA, 2003). The EPA, NRCA, and the Departments of Energy and Defense jointly sponsored a review of the underlying science by the NRC.

Response: EPA's determination to regulate perchlorate is based upon the National Research Council's 2005 (NRC, 2005) recommendation to use data from a human clinical study (Greer et al. 2002) as a basis for the human health risk assessment, and as a basis for the current RfD. On August 19, 2009, EPA published a FR Notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (FR Vol. 74, No. 159, p. 41883). In this August 19, 2009 FR Notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard. EPA has considered and discusses in the FR Notice the human health effects of perchlorate. The Agency analyzed the additional information received, and EPA has determined that perchlorate meets the criteria for regulating a contaminant in drinking water under Section 1412(b)(1)(A) of SDWA. See comment code 5000, 5100, 5200 and 5300 for further discussion of the criteria for a regulatory determination and EPA's decision to regulate perchlorate. Greer MA, Goodman G, Pleus RC, Greer SE. Health effects assessment for environmental perchlorate contamination: the dose response for inhibition of thyroidal radioiodine uptake in humans. Environ Health Perspect. 2002 Sep;110(9):927-37. EPA Comment Code: 2000

Comment: A 1 ppb or lower MCL is supported by the most recent comprehensive studies, and these should be central to EPA's analysis. The industry-supported Greer study, which serves as the basis for EPA's current reference dose consisted of a 14-day study of 37 healthy adults. In more recent years, Blount et al analyzed a nationally representative sample of 2299 U.S. residents, and they have documented anti-thyroid effects in a large population of women exposed to perchlorate at concentrations far lower than levels previously shown to have such effects. This study and subsequent data clearly justify promulgation of a more protective MCL.

Response: On October 10, 2008, EPA published a FR Notice requesting public comments on its preliminary determination not to regulate perchlorate in drinking water (FR Vol. 73, No. 198, p. 60266). EPA has considered and discusses in the FR Notice the results of the Greer et al. (2002), and Blount et al. (2006) studies, in the process of evaluating the adverse health effects of perchlorate. The Blount et al. (2006) study investigated adverse effects of perchlorate exposure with women with urinary iodine below 100 ug/L, and revealed adverse thyroid hormone effects in women whose urinary iodine was below 100 ug/L, which is suggestive of a partial study population iodine deficiency status. EPA published additional analyses of these and other studies in August 2009. In this final determination, EPA evaluated the best available peer-reviewed science, and the

Agency has determined to regulate perchlorate in drinking water. An appropriate level for regulation has not yet been determined.

EPA Comment Code: 2000

Comment: In the Notice EPA describes alternative interpretations of health and exposure data for perchlorate that may impact EPA's final regulatory determination for perchlorate. EPA seeks comments on these alternatives in three areas:

* interpretation of physiologically-based pharmacokinetic (PBPK) modeling;

* derivation of alternative health reference levels (HRLs) based on body weight and water consumption rates for sensitive life stages; and

* use of data on perchlorate occurrence in drinking water.

To provide context for these comments, several points regarding the availability of scientific data on perchlorate are important. First, substantial research and evaluation of the potential health effects of perchlorate have been conducted. The scientific literature represents more than five decades of scientific inquiry. Since EPA began evaluating perchlorate in the early 1990s, scientists from government, industry, and academia have made important contributions to reducing uncertainties about the risks of perchlorate to public health (see footnote 4). In response to EPA's request for comment on its preliminary determination, Intertox reviewed the existing data (Intertox, 2008).[FN4: These comments were in response to the EPA FR notice Drinking Water: Preliminary Regulatory Determination on Perchlorate (U.S. EPA, 2008a).] Briefly, these data include:

* the 2005 NRC assessment of perchlorate and update of key studies that have been added to the scientific literature;

* at least twelve animal toxicological studies conducted between 1997 and 2002, all using EPA protocols, including pharmacokinetic, subchronic, developmental, and immunotoxicology studies, and a multigenerational reproductive study, conducted using a range of doses, and evaluated independently by EPA;

* several clinical and occupational exposure studies in humans and a number of epidemiologic and ecological studies between 1997 and 2002, some in occupational settings and some in populations exposed to perchlorate via the community drinking-water supply; and

* additional studies conducted since 2002, adding to the scientific literature.

Other agencies, e.g., the ATSDR (2008), have also conducted rigorous reviews of the scientific literature regarding the potential for adverse health effects from perchlorate exposure and have determined that doses equivalent to the current RfD are health protective.

Second, a no observed effect level (NOEL) has been identified for perchlorate exposure in humans. At the lowest dose of Greer et al. (2002) (the basis of the perchlorate RfD), there was no statistical difference in iodide uptake inhibition (IUI), a nonadverse effect, for subjects before and after a dose of 0.007 mg/kg-d (245 ppb assuming default body weight and drinking water intake).[FN5: The actual variable measured in Greer et al. (2002) was radioactive iodide uptake or RAIU.] As the NRC (2005) states with emphasis, "Inhibition of iodide uptake by the thyroid clearly is not an adverse effect; however if it does not occur, there is no progression to adverse health effects." Use of a NOEL is more conservative than EPA's common approach using the no observable adverse effect level (NOAEL) or the lowest observable adverse effect level (LOAEL).

Third, perchlorate is water soluble, has a half life in humans of approximately eight hours, and does not bioaccumulate. Because perchlorate has a short half life, some have questioned whether exposure to perchlorate might cause an acute effect. Toxicologically speaking, "acute" describes effects seen after one high dose or an exposure of less than 24 hours. No published study has demonstrated an effect after one exposure to perchlorate at environmental levels. The dose required for acute effects would require therapeutic levels; the medical literature reports that doses from 200 mg to over 1 gram given on a daily basis (the equivalent of 100,000 to 500,000 ppb in drinking water using standard EPA default assumptions[FN6: 1g = 1,000 mg; Drinking Water Equivalent for 1,000 mg perchlorate / 2 L of water per day = 500 mg/L or 500 ppm or 500,000 ppb; Drinking Water Equivalent for 200 mg would be 100 ppm or 100,000 ppb.]) are necessary to cause side effects (e.g., nausea and gastrointestinal upset at lower doses to aplastic anemia and agranulocytosis at daily doses of one gram or more) in 5 to 18 percent of study populations (NRC, 2005; Barzilai and Sheinfeld, 1966). At exposures lasting several weeks to months (more commonly termed "subchronic"), the scientific literature does not demonstrate any evidence of adverse effect. Thyroxine (T4) has a half life of 6-8 days and must be sufficiently depleted for developmental effects to occur. A single perchlorate dose in excess of 1 gram per day would most likely cause some frank toxicity, but based on the science to date, will not decrease serum thyroid hormone levels without daily exposure for weeks.

Fourth, the NRC's recommendation to base the RfD on a NOEL was conservative and health protective, as this dose is lower than any dose at which adverse effects may occur. To derive the RfD, the NOEL was divided by an uncertainty factor (UF) of 10 to account for the most sensitive individuals in a population, the hypothyroid or iodine-deficient pregnant women and their developing fetuses. The NRC committee stated that using a NOEL as the point of departure (POD) is a more conservative and health protective approach than EPA's customary approach of using the adverse effect (NRC, 2005). For example, the use of the threshold for IUI as a POD is more conservative and health protective than using changes in thyroid hormones (also a precursor to possible adverse effects) or an adverse effect such as hypothyroidism.

Perchlorate's reversible inhibition of the NIS is documented in many experiments, both in vivo and in vitro. This interaction exhibits the standard sigmoidal dose-response curve in toxicology and pharmacology-as dose increases, so does the response. There is no scientific evidence to suggest that low doses of perchlorate will cause any other effect. Perchlorate competitively inhibits iodide uptake; it neither mimics a hormone nor directly stimulates a response.

Response: See response to comment code 2000.

EPA Comment Code: 2100 NAS (NRC) review of perchlorate health effects and reference dose

Response to Comment Code 2100: On October 10, 2008, EPA published a Federal Register notice presenting the Agency's preliminary regulatory determination for perchlorate and supporting rational for this determination, in accordance with the Safe Drinking Water Act (SDWA) (Federal Register Vol. 73, No. 198, p. 60262). In this October 10, 2008 Federal Register notice, EPA determined that a national primary drinking water regulation (NPDWR) for perchlorate would not present a meaningful opportunity for health risk reduction for persons served by public water systems. In 2003, the National Research Council (NRC) of the National Academy of Sciences (NAS) was asked by EPA to assess the current state of the sciences regarding potential adverse effects of perchlorate exposure in human and animals, and to determine whether EPA's prior perchlorate risk assessment findings were consistent with current scientific evidence. In a NRC 2005 review of the state of the sciences regarding potential perchlorate adverse health effects and mode-of-action ("Health Implications of Perchlorate Ingestion", NRC 2005), the NRC recommended that data from the Greer et al. (2002) human clinical study be used as the basis for deriving a perchlorate reference dose (RfD)(NRC 2005). From this Greer et al. (2002) human clinical study, the statistical no observed effect level (NOEL) for the perchlorate-induced inhibition of thyroid iodide uptake was determined to be 7.0 ug/kg, which corresponded to an iodide uptake inhibition of 1.8 %. The NRC concluded that the most health protective and scientifically valid approach to deriving a reference dose for perchlorate was to base the perchlorate RfD on the inhibition of iodide uptake by the thyroid, and that iodide uptake inhibition, though not an adverse effect per se, is the most appropriate precursor event, and would precede any more severe adverse health effects of perchlorate exposure in humans. The NRC recommended basing the RfD on a precursor to an adverse effect rather than an adverse effect per se. The precursor event precedes a downstream adverse effect in the dose response continuum. In this case, NRC used prevention of iodide uptake inhibition, a precursor to adverse thyroid effects, to establish a level at which no adverse effects would be anticipated in exposed populations. This approach is consistent with the Agency's policy on the use of precursor events when appropriate in establishing the critical effect upon which an RfD is based (U.S. EPA, 2002). The NRC recommended that EPA apply an uncertainty factor of 10 to this NOEL of 7.0 ug/kg for the perchlorate-induced inhibition of thyroid iodide uptake, to account for differences in sensitivity between healthy adults and the most sensitive sub-population, consisting of fetuses of pregnant women who might have hypothyroidism or iodide deficiency. The NRC viewed the recommended uncertainty factor of 10 as conservative and protective of health, given that the NOEL is based on a non-adverse effect (iodide uptake inhibition) which precedes the adverse effect in a continuum of possible adverse biological effects of perchlorate exposure. NRC recommended that using a non-adverse effect that is upstream of the adverse effect represents a more conservative, health-protective approach to the risk assessment for perchlorate, noting that the purpose of the 10-fold uncertainty factor is to protect sensitive subpopulations in the face of uncertainty regarding their relative sensitivity to perchlorate exposure. EPA has adopted the NRC's recommendations in its "Integrated Risk Information System" (IRIS) (USEPA 2005), resulting in an RfD of 0.7 ug/kg/day, which was derived by applying a 10-fold (10x) uncertainty factor to the NOEL of 7.0 ug/kg/day.

EPA believes the NRC appropriately based the RfD on iodide uptake inhibition to the thyroid, for the reasons discussed in its report. EPA notes that the data underlying the definition of iodide uptake inhibition as a precursor effect and the relationship of iodide uptake inhibition to the

continuum of adverse outcomes reflects an understanding of effects in adults; it may not reflect the relationship of the precursor event to adverse outcomes in neonates and infants, who may not have iodide stores sufficient to offset the effects of reduced iodide uptake. The less resilient neonatal and infant system makes the exposure gap between a precursor event (iodide uptake inhibition due to perchlorate) and reduced T3/T4 levels likely to be narrower than for adults, and in fact, the distinction between the two may be blurred for the very young (Greer et al., 2002; Savin et al., 2003; van den Hove et al., 1999). The NRC noted that, "[T]he minimal prolonged decrease in thyroid hormone production that would be associated with adverse health effects is not known; any decrease is potentially more likely to have adverse effects in sensitive populations (people with thyroid disorders, pregnant women, fetuses, and infants) but data are not available to determine the magnitude of the decrease needed to cause adverse effects in those populations."

EPA Comment Code: 2100

Comment: We note that the RfD itself is uncertain and is not necessarily a health protective benchmark. It is based upon a limited clinical study of short duration and small sample size not representative of the variability in the human population (Greer, et al., 2002). When a larger epidemiologic study was conducted by CDC, significant correlations were found between increasing perchlorate exposure and decreasing thyroid hormone levels in the subpopulation of women with low iodide intake, which the CDC NHANES data show constitutes 31% of all women (Blount, et al 2006). The exposure levels associated with anti- thyroid effects in these women were below the perchlorate RfD. These findings cast doubt on the protectiveness of the RfD, and make it especially important that no group exceed this health benchmark.

Comment: Exposure

In addition to occurrence, the evaluation criteria in the SDWA also consider whether contamination is occurring at levels "of public health" concern and whether regulation of the contaminant would meaningfully reduce potential health risks. AWWA would like to acknowledge and compliment the National Research Council for the extensive assessment of risk that resulted in setting the oral Reference Dose (RfD) at 7x10-4 mg/kg-day. In consideration of the SDWA criteria, it should be emphasized that the RfD represents a No Observed Effect Level (NOEL) versus the more traditional No ObservedAdverse Effect Level (NOAEL). As discussed by Crawford-Brown et.al.

(2006) and in the proposed decision, a NOAEL is by definition equal to or higher than a NOEL wherethe effect used to establish the NOEL is a precursor to the adverse effect of interest in establishing a NOAEL. The NRC's use of a precursor to an adverse effect (iodine uptake inhibition) in establishing a threshold for exposure represents a "more conservative, health-protective approach". This assures the protection of the sensitive subpopulation (iodide-deficient pregnant women and their fetuses) and mitigates the need for additional uncertainty factors to be applied.

Response: EPA does not agree that use of precursor effect alters the need for uncertainty factors. Uncertainty factors are applied to respond to specific aspects of uncertainty in some aspect of the health assessment, regardless of the nature of the endpoint used. Examples include intraspecies or interspecies variability, data gaps, or discrepancies in time course of the study compared to the anticipated effect/exposure profile in the public. Also, see response to comment code 2100.

Comment: Perchlorate interferes with iodide uptake and affects the release of thyroid hormones. Appropriate levels of thyroid hormones are critical to the development of the brain and other organs, making the fetus and newborn infant particularly sensitive to perchlorate toxicity. Maternal exposure to elevated levels of perchlorate has been linked to mild, in some cases severe and irreversible, neurological outcomes in infants. Perchlorate is but one more contaminant along with mercury, PCBs, PBDEs, and lead that adversely impact the developing brain.

Washington Department of Health and Oregon Department of Human Services, Public Health Division believe that the 10-fold uncertainty factor used by EPA to derive a Reference Dose (RfD), and its subsequent use to formulate a health based drinking water level, is insufficient.

We believe that due to the data gaps in the limited studies available for perchlorate that a higher uncertainty factor is warranted. Back in 2002, EPA more appropriately utilized a higher uncertainty factor in the agency's assessment of perchlorate, as did the state of Massachusetts in their in-depth risk assessment of perchlorate. Exposure estimates based on a more protective RfD indicate that, at any one time, as many as 210,000 pregnant women in the US are exposed to unsafe levels of perchlorate. This view of risk could well influence the conclusion as to whether or not a national regulation of percholorate in drinking water presents a meaningful opportunity to protect public health.

As state regulators, we strive to evaluate chemical hazards in a consistent manner. If EPA had used its standard risk assessment methodology, their findings of the hazards of perchlorate in drinking water would have been significantly different. We recommend that EPA reconsider its evaluation since there is no obvious scientific reason for using the different methodology which led to this preliminary determination.

We support the scientific approach reflected in the enclosed information prepared by the Washington Department of Health, and ask that EPA carefully consider it as your agency

determines the appropriate next step. Further, if we can provide any further information regarding this important public health issue, please contact us, Gregg Grunenfelder, Washington State Department of Health, (360.236.3050) or Gail Shibley, Oregon State Department of Human Health Services (971.673.0400).

Sincerely,

Gregg Grunenfelder, Assistant Secretary Washington State Department of Health Division of Environmental Health

Gail R. Shibley, Administrator Oregon State Department of Human Services Office of Environmental Public Health

Comment: Enclosure

November 10, 2008 Docket ID No. EPA-HQ-OW-2008-0692 Comments on EPA's Preliminary Regulatory Determination for Perchlorate Prepared by Washington State Department of Health

On October 10, 2008, the US Environmental Protection Agency (EPA) placed an action notice on the Federal Register [FN1: EPA 2008. Fact Sheet: Preliminary Regulatory Determination for Perchlorate. Office of Water. United States Environmental Protection Agency. EPA 815-F-08-009. October 2008.],[FN2: Federal Register: October 10, 2008 (Volume 73, Number 198). Notices. Page 60262-60282. From the Federal Register Online via GPO Access [wais.access.gpo.gov] [DOCOD:fr10oc08-66].] relating to preliminary regulatory determination for perchlorate in accordance with the federal Safe Drinking Water Act. The agency determined that a national primary drinking water regulation for perchlorate would not present "a meaningful opportunity for health risk reduction for persons served by public water systems." EPA will make a final regulatory determination for perchlorate after considering public comments and information provided during the 30-day comment period ending November 10, 2008. EPA intends on publishing its final regulatory determination in December 2008 to provide state and local public health officials with technical information that can be used to address local contamination.

Perchlorate (ClO4) is a naturally occurring inorganic compound that can also be manufactured. Ammonium perchlorate (NH4ClO4), is a salt used as an oxidizer in rocket propellants and fireworks. It has also been found in certain fertilizers, and was used in the past as a medicine to treat hyperthyroidism (overactive thyroid) in humans. Perchlorate salts are ionic and dissociate completely when dissolved in water. The soluble anion ClO4 has been found in groundwater in many states where testing has occurred. To date, it is not clear to what extent perchlorate is found in groundwater across the United States, because it has not been widely studied. In the northwest, low

levels of perchlorate have been found in groundwater in some tested areas of eastern Washington and Oregon.

Perchlorate interferes with the thyroid's ability to take in iodide. The thyroid needs iodide to produce certain hormones that are necessary for numerous body functions. If the thyroid is unable to produce enough of these hormones, a condition known as hypothyroidism (underactive thyroid disease) may result. Thus, perchlorate exposure has the potential to result in hypothyroidism.

All people are susceptible to perchlorate's effects on the thyroid (decreased iodide uptake), but pregnant women, infants, children, and people with low iodide intake in the diet, or pre-existing thyroid problems may be more susceptible. Hypothyroidism, if untreated, can lead to numerous health effects including, fatigue, muscle aches, unexplained weight-gain, depression, and many other symptoms. Moreover, hypothyroidism in pregnant women (developing fetuses), infants, and children can lead to impaired mental and physical development. Maternal exposure to elevated levels of perchlorate has been linked to mild, and in some cases severe and irreversible neurological outcomes in infants. Similar adverse outcomes to the developing fetus have been documented with exposure to mercury, PCBs, PBDEs, and lead.

In the absence of federal regulatory standards on perchlorate, several states have developed Reference Doses (RfD) or safe doses that are used to derive safe drinking water guidance or standards. Most notably are recent efforts by EPA [FN3: EPA 2002. Perchlorate environmental contamination: toxicological review and risk characterization. External Review Draft. United States Environmental Protection Agency. Office of Research and Development. NCEA-1-0503. January 16, 2002.], California [FN4: Ting D, Howd RA, Fan AM, and Alexeeff GV. 2006. Development of a Health-Protective Drinking Water Level for Perchlorate. Environmental Health Perspectives (114)6: 881-86.],[FN5: California Environmental Protection Agency. 2004. Office of Environmental Health Hazard Assessement. Public Health Goals for Chemicals in Drinking Water: Perchlorate. March 2004.], New Jersey [FN6: New Jersey Department of Environmental Protection 2005. New Jersey Drinking Water Quality Institute. Maximum Contaminant Level Recommendation for Perchlorate. October 7, 2005.], Massachusetts [FN7: Massachusetts Department of Environmental Protection. 2006. Office of Research and Standards. Update to "Perchlorate Toxicological Profile and Health Assessment". March 2006.], and the National Research Council of the National Academy of Science (NAS) [FN8: National Academy of Sciences. 2005. Health Implication of Perchlorate Ingestion. National Academies Press. Washington D.C. Available at URL: http://www.nap.edu/catalog.php?record_id=11202].

EPA conducted the initial draft toxicological review of perchlorate in 2002, resulting in a proposed RfD of 0.00003 mg/kg/day based primarily on studies that identified neurodevelopmental deficits in rat pups [FN9: Argus 2001. Hormone, thyroid, and neurohistological effects of oral (drinking water) exposure to ammonium perchlorate in pregnant and lactating rats and in fetuses and nursing pups exposed to ammonium perchlorate during gestation or via maternal milk. Argus Research Laboratories, Inc. Horsham, PA. Protocol no. ARGUS 1416-003. Cited in EPA 2002.]. These deficits were linked to maternal exposure to perchlorate. Subsequent to this assessment, California, New Jersey, the NAS, and Massachusetts reviewed the health implications of perchlorate, and each proposed an alternative reference dose of 0.0004, 0.0007, 0.0007, and 0.00003 mg/kg/day, respectively. This is based primarily on a study on humans conducted by Greer et al. published in 2002. A summary of perchlorate reference doses developed by the various agencies is presented in Table 1.

[Table 1. Comparison of Perchlorate Reference Doses (RfD) Developed by Other Agencies - see PDF Docket ID EPA-HQ-OW-2008-0692-1259]

In the Greer et al. [FN10: Greer MA, Goodman, F, Pleus RC, and Greer SE. 2002. Health Effects Assessment for Environmental Perchlorate Contamination: The Dose Response for Inhibition for Thyroid Radioiodine Uptake in Humans. Environmental Health Perspectives (110)9: 927-37.] study cited by four of the five agencies, 37 human subjects were split into four exposure groups and administered oral doses of perchlorate at 0.007 (7 subjects), 0.02 (10 subjects), 0.1 (10 subjects), and 0.5 (10 subjects) mg/kg/day. Significant decreases in iodide uptake were found in the three highest exposure groups. Iodide uptake was not significantly reduced in the lowest exposed group, but four of the seven subjects in this group experienced inhibited iodide uptake. The RfD proposed by NAS was accepted by EPA and added to its integrated risk information system (IRIS) in 2005.

Much debate was generated following EPA's posting of the RfD in IRIS, most notably in commentary submitted to the journal Environmental Health Perspectives by Ginsberg and Rice [FN11: Ginsberg G and Rice D. 2005. The NAS Perchlorate Review: Questions Remain about the Perchlorate RfD. Environmental Health Perspectives (115)3: 361-69.]. The authors argued that the RfD was not adequately protective of human health for the following reasons:

1. The NAS report described the level of lowest exposure from Greer et al. as a no observed effect level (NOEL). However, there was actually an effect at that level although not statistically significant largely due to small size of study population (four of seven subjects showed a slight decrease in iodide uptake).

2. Reduced iodide uptake was not considered an adverse effect. However, it is a precursor to an adverse effect (hypothyroidism). Therefore, additional safety factors are necessary when extrapolating from the point of departure to the RfD.

3. Consideration of data uncertainty was insufficient because the Greer, et al. study reflected only a 14-day exposure to healthy adults and no additional safety factors were considered to protect sensitive subpopulations. For example, the potential for greater toxicity to breastfeeding newborns was not considered.

Response: EPA believes that the RfD recommended by the NAS remains appropriate, as discussed in the other responses to comments in this section (comment code 2100); however, EPA will be continue to evaluate scientific studies of perchlorate health effects as the Agency develops the National Primary Drinking Water Regulation for perchlorate.

Comment: The Department of Health's Conclusions:

There is consensus among agencies that the Greer et al. study is appropriate for deriving the RfD, but there is not consensus with regard to developing drinking water maximum contaminant levels (MCLs) or action levels. One of the key differences results from how the point of departure is viewed [i.e., No observed effect level (NOEL) or lowest observed adverse effect level (LOAEL)], or whether a benchmark dose should be used to derive the RfD. Defining the point of departure as a NOEL or LOAEL has implications when it comes to applying appropriate safety factors to the point of departure to derive the RfD.

Based on a review of existing literature, the Department of Health has identified the following concerns with EPA's perchlorate action level:

* EPA's RfD, which is the basis for the health reference level, may not be protective of public health with a reasonable margin of safety.

Response: Please see response to comment code 2100 for a discussion of the RfD. See Response to comment code 5220 for a discussion of alternative Health Reference Levels. EPA will continue to refine its analyses for purposes of proposing an MCL and MCLG. EPA plans to seek comment on the proposed national drinking water regulation pursuant to the requirements of the Safe Drinking Water Act.

EPA Comment Code: 2100

Comment: We also found critical errors in the selection, design and interpretation of the studies that were included in docket ID No. EPA-HQ-OW-2008-0692. The irrelevant studies should be dropped from the docket, the flawed interpretations of the remaining studies should be corrected, and the conclusions drawn revised.

Several studies reported in docket ID No. EPA-HQ-OW-2008-0692 are either inappropriate for inclusion, or erred in their design or interpretation. Most significant in this regard is the population that was emphasized by the EPA in citing the NAS report of 2005 (NRC, 2005): pregnant adults. EPA provided no scientific justification for this emphasis. Moreover, the emphasis on the pregnant adult illustrates the mistake of public health recommendations by persons who are not at significant risk. As we've noted above: "the adult thyroid system appears capable of significant compensation for low thyroid hormone levels, and the consequences of low thyroid hormone are likely to be reversible."

Response: EPA respectfully disagrees with the commenter. It is also noted that the commenter does not specify which studies she is critical of. In a NRC 2005 review of the state of the sciences regarding potential perchlorate adverse health effects and mode-of-action ("Health Implications of Perchlorate Ingestion", NRC (2005)), the NRC recommended that data from the Greer et al. (2002) human clinical study be used as the basis for deriving a perchlorate reference dose (RfD) (NRC 2005). From this Greer et al. (2002) human clinical study, the statistical no observed effect level (NOEL) for the perchlorate-induced inhibition of thyroid iodide uptake was determined to be 7.0 ug/kg, which corresponded to an iodide uptake inhibition of 1.8%. The NRC concluded that the

most health protective and scientifically valid approach to deriving a reference dose for perchlorate was to base the perchlorate RfD on the inhibition of iodide uptake by the thyroid, and that iodide uptake inhibition, though not an adverse effect per se, is the most appropriate precursor event, and would precede any more severe adverse health effects of perchlorate exposure in humans. The NRC recommended basing the RfD on a precursor to an adverse effect rather than an adverse effect per se. The precursor event precedes a downstream adverse effect in the dose response continuum. In this case, NRC used prevention of iodide uptake inhibition, a precursor to adverse thyroid effects, to establish a level at which no adverse effects would be anticipated in exposed populations. This approach is consistent with the Agency's policy on the use of precursor events when appropriate in establishing the critical effect upon which an RfD is based (U.S. EPA, 2002). The NRC recommended that EPA apply an uncertainty factor of 10 to this NOEL of 7.0 ug/kg for the perchlorate-induced inhibition of thyroid iodide uptake, to account for differences in sensitivity between healthy adults and the most sensitive sub-population, consisting of fetuses of pregnant women who might have hypothyroidism or iodide deficiency. Iodide uptake inhibition has been identified in the literature as an area of concern in connection with increasing the risk of neurodevelopmental impairment in fetuses of high-risk mothers. The NRC viewed the recommended uncertainty factor of 10 as conservative and protective of health, given that the NOEL is based on a non-adverse effect (iodide uptake inhibition) which precedes the adverse effect in a continuum of possible adverse biological effects of perchlorate exposure. NRC recommended that using a non-adverse effect that is upstream of the adverse effect represents a more conservative, health-protective approach to the risk assessment for perchlorate, noting that the purpose of the 10-fold uncertainty factor is to protect sensitive subpopulations in the face of uncertainty regarding their relative sensitivity to perchlorate exposure. EPA has adopted the NRC's recommendations in its "Integrated Risk Information System" (IRIS) (USEPA, 2005), resulting in an RfD of 0.7 ug/kg/day, which was derived by applying a 10-fold (10x) uncertainty factor to the NOEL of 7.0 ug/kg/day. Commenter Name: Michael Dourson
Commenter Organization: Toxicology Excellence for Risk Assessment
EPA Document ID: EPA-HQ-OW-2008-0692-1562
EPA Comment ID: 20641
EPA Comment Code: 2100

Comment: Our primary concern is related to the RfD EPA used to estimate Health Reference Level. Our comments follow three lines of evaluation:

1. Critically important data on pregnant women and their offspring have become available since the time of the development of the EPA RfD in 2005 (EPA, 2008), which necessitate a reconsideration of the existing value. This reconsideration is consistent with recommendations of the NAS (2005) on page 69 of its report.

2. The excellent relative source contribution evaluation of EPA, based on well supported and clearly described work of the FDA, necessitates a rethinking of the EPA's RfD, since the subjects in Greer et al. (2002) on which it was based undoubtedly had unmeasured perchlorate in their food.

3. The 2005 NAS "RfD" does not follow the existing EPA RfD method.

All three of these arguments are more fully discussed below. We also offer a commentary on the Blount et al. (2007) that may have some bearing on this federal action (Attachment A). Note, while a reanalysis of the RfD will not have an effect on the regulatory conclusion discussed in this Federal Register notice, it will have an effect on the Health Advisory that EPA derives, which will be used by States for their regulation of perchlorate.

Response: See response to comment ID 20957 under comment code 2100 for a discussion of adjusting the Greer study to account for perchlorate which may have been in subjects' food. EPA supports the review and evaluation of additional new data regarding the health effects of perchlorate. However EPA respectfully disagrees with the commenter regarding the NRC (2005) recommendations for the RfD, as discussed below. EPA will continue to evaluate scientific studies of perchlorate health effects as part of the perchlorate rulemaking

The EPA "Integrated Risk Information System" (IRIS) employs EPA's standard risk assessment methodology. The RfD, which is derived from the NOEL, is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population that is likely to be without an appreciable risk of deleterious effects during a lifetime. The RfD, based on the assumption that thresholds exist for certain toxic effects of chemicals, represents the drinking water perchlorate exposure plus an incremental additional exposure of perchlorate from either water or food which could trigger iodine uptake inhibition, with a 10X safety factor applied. The NRC recommended that data from the Greer et al. (2002) human clinical study be used as the basis for deriving a perchlorate reference dose (RfD) (NRC 2005), and also noted that the results of this study were supported by those of other human studies. From this Greer et al. (2002) human clinical study, the statistical no observed effect level (NOEL) for the perchlorate-induced inhibition of thyroid iodide uptake was determined to be 7.0 ug/kg (a corresponding iodide uptake inhibition of 1.8%). The NRC concluded that the most health protective and scientifically valid approach was to base the perchlorate RfD on the precursor event of inhibition of iodide uptake by the thyroid. This approach is consistent with the Agency's policy on the use of precursor events when appropriate in establishing the critical effect upon which an RfD is based (U.S. EPA, 2002). The NRC recommended that EPA apply an uncertainty factor of 10 to this NOEL of 7.0 ug/kg to account for differences in sensitivity between healthy adults and the most sensitive sub-population (fetuses of pregnant women who might have hypothyroidism or iodide deficiency). Iodide uptake inhibition due to perchlorate exposure has been identified as an area of concern in connection with increasing the risk of neurodevelopmental impairment in fetuses of high-risk mothers. The NRC viewed the recommended uncertainty factor of 10 as conservative and protective of health. NRC recommended that using a non-adverse effect that is upstream of the adverse effect represents a more conservative, health-protective approach to the risk assessment for perchlorate, noting that the purpose of the 10-fold uncertainty factor is to protect sensitive subpopulations in the face of uncertainty regarding their relative sensitivity to perchlorate exposure. EPA has adopted the NRC's recommendations in its "Integrated Risk Information System" (USEPA, 2005), resulting in an RfD of 0.7 ug/kg/day, which was derived by applying a 10-fold uncertainty factor to the NOEL of 7.0 ug/kg/day. EPA

used the best available peer-reviewed science, and the Agency has determined to regulate perchlorate in drinking water.

Comment: Availability of New Data

Critically important data on pregnant women and their offspring have become available since the time of the development of the 2005 EPA's Reference Dose (RfD) (EPA, 2008), which necessitate a reconsideration of the existing value.

For example, although the NAS recommended that the Greer et al (2002) be used as the basis of the RfD, the NAS also recognized that new, useful data were under development:

"On the basis of the iodide-inhibition analyses, the additional comparisons, and a review of information on urinary iodide excretion, the committee concluded that the data from Chile could be considered in the evaluation of the U.S. experience with perchlorate in drinking water." (NAS, 2005, page 69)

The data to which NAS referred was published prior to the NAS report as Crump et al. (2000), and after the NAS report as Tellez et al. (2005), the abstract of which reads:

"We have conducted a longitudinal epidemiologic study among pregnant women from three cities in northern Chile: Taltal with 114 ug/L, Chañaral with 6 ug/L, and Antofagasta with 0.5 ug/L perchlorate in the public drinking water. We tested the hypothesis that long-term exposure to perchlorate at these levels may cause a situation analogous to iodine deficiency, thus causing increases in thyrotropin (TSH) and thyroglobulin (Tg) levels and decreased levels of free thyroxine (FT4), in either the mother during the early stages of gestation or the neonate at birth, or in the fetus cause growth retardation. We found no increases in Tg or TSH and no decreases in FT4 among either the women during early pregnancy (16.1 +/- 4.1 weeks), late pregnancy (32.4 +/- 3.0 weeks), or the neonates at birth related to perchlorate in drinking water. Neonatal birth weight, length, and head circumference were not different among the three cities and were consistent with current U.S. norms. Therefore, perchlorate in drinking water at 114 ug/L did not cause changes in neonatal thyroid function or fetal growth retardation. Median urinary iodine among the entire cohort was 269 ug/L, intermediate between that of pregnant women in the United States at National Health and Nutrition Examination Survey (NHANES) I and at NHANES III and consistent with current World Health Organization (WHO) recommendations. Median breast milk iodine was not decreased

in the cities with detectable perchlorate. Analysis of maternal urinary perchlorate excretion indicates an additional dietary source of perchlorate." (Tellez et al., 2005)

In addition, EPA has discussed other data relevant to deriving an updated RfD in this Federal Register notice, including Amitai et al., 2007, Blount et al., 2006b (see a separate discussion of Blount in Attachment A), and the studies discussing PBPK models (Merrill et al., 2005; Clewell et al., 2007).

Contribution of Perchlorate in Food to Total Exposure

As EPA discussed in this Federal Register notice, the US population is being exposed to perchlorate through both food and water. Based on EPA's excellent relative source contribution evaluation (Table 6), the dose of perchlorate from food could range from 0.075 ug/kg-day (median dose) to 0.167 ug/kg-day (90th percentile dose) and account for 24% of total perchlorate exposure for the general population.

This information may necessitate a rethinking of the 2005 RfD based on Greer et al. (2002). Since these investigators did not measure perchlorate in the food of the human subjects, it is likely the total perchlorate dose received by the subjects was higher than the drinking water dose of 0.007 mg/kg-day that was used as the point of departure for the RfD. This same consideration might also be appropriate for RfDs based on other human studies.

The 2005 NAS "RfD" does not follow the existing EPA RfD method.

While we agree that perchlorate causes adverse effects in the manner described by EPA, and that EPA based its Reference Dose (RfD) principally on the work of the NAS/NRC (2005), and further that the NRC (2005) provided an insightful and conclusive discussion of perchlorate science, it is exceedingly clear that NRC did not use accepted risk assessment methods, nor EPA methods, to develop a reference dose. NRC concluded that hypothyroidism would be the first observed adverse effect, or critical effect (Faustman, and Omenn. 2001; EPA, 2008), and that the dose level at which this effect would likely first be observed (the no observed adverse effect level, or NOAEL) in healthy adults is 0.4 mg/kg-day. This choice might be appropriate basis of the RfD.

Yet, NRC selected the lowest of several precursors to this lowest adverse effect, the threshold of iodine uptake inhibition, as the starting point for its reference dose (RfD), because it was "more health protective". As NRC clearly stated, this effect of itself does not result in any harm, and the dose at which it occurs is approximately 100 times lower than the NOAEL of the first adverse effect. Moreover, this choice of lowest precursor is not consistent with EPA guidelines.

Specifically, NRC ignores two principles that govern calculating RfDs: 1. To identify an intake that "reduces hazard to a minimum and at the same time allows use of [necessary] chemicals ((Faustman, and Omenn. 2001)," and 2. To base RfDs on an adverse effect (Lehman and Fitzhugh, 1954), or an adverse effect or its precursor (Barnes and Dourson, 1988; EPA, 2002).

That is, the definition of critical effect by EPA specifies an adverse effect or its precursor---singular---meaning the penultimate precursor when several are available. Thus, the RfD has been, and must continue to be, the largest intake that can be reasonably certain to cause no injury to the whole

population. Otherwise, there is no reason not to choose lower precursors for any RfDs, resulting in RfDs that solely depend on how many precursor effects have been monitored.

The practice of focusing on the first adverse effect, or its known precursor, in dose response assessment, is based on decades of experience in the United States, Canada, and Europe. This practice allows us to draw conclusions about public health in the absence of observable data and in the presence of scientific uncertainty. The accepted process for developing RfDs (Barnes and Dourson, 1988) suggests two possible approaches to developing an RfD from the perchlorate data. The first would be to use the NOAEL of the critical effect from an adult population and apply uncertainty factors to account for sensitive populations and for lack of precision in defining this NOAEL. The second approach would be to use a NOAEL from a sensitive population.

Following this second approach, a standard RfD of 0.002 mg/kg-day has been described that is adequately health-protective (Strawson et al., 2004). This RfD may be suitably upgraded with the use of the newer epidemiology studies, as described briefly above.

Using a non-standard RfD process in regulating chemicals, such as that suggested by NAS (2005) for perchlorate, is not consistent with accepted EPA methods for developing such values. EPA's acceptance of this non-standard RfD undermines its good dose response assessment work in other programs.

Comment: However, we also recommend that EPA update its RfD prior to publishing a Health Advisory for the following reasons:

Additional important data on pregnant women and their offspring have become available since the time of the development of the EPA's RfD in 2005, which necessitate a reconsideration of the existing value. This reconsideration is consistent with recommendations of the NAS (2005) in its report.

The excellent relative source contribution evaluation of EPA, based on well supported and clearly described work of the FDA, necessitates a rethinking of the any RfD, since the underlying studies may not have measured perchlorate in the food of the human subjects.

The 2005 "RfD" of the NAS does not follow the existing EPA method.

Additional information is provided in the attached document.

Comment: III (A)(1 and 2), pp 60266-60268. The NRC (2005) review of the Greer et al. (2002) study is discussed. EPA notes that the lowest dose of 7 ug/kg-day in the Greer et al. study corresponds to a statistical NOEL, and suggests that an uncertainty factor of 10 from the lowest dose is adequate to derive a health- protective level of 0.7 ug/kg-day, to account for human variability, as recommended by the NTP review panel. However, OEHHA would like to point out that the data also allow calculation of the lower confidence limit on a benchmark dose level for inhibition of iodide uptake. Using the lower 95% confidence limit of a 5% benchmark dose for inhibition of iodide uptake, OEHHA calculated a BMDL of 3.7 ug/kg-day, using EPA BMDS software (OEHHA, 2004). Although the low number of subjects (37) in the Greer et al. study cannot provide an accurate estimate of true human variability, it seems to us that using the available data in this calculation is a more reasonable way to account for the uncertainty in the data than just dividing the NOEL by 10. Our approach in fact follows the recommendations of EPA as to when BMD modeling should be applied.

It should also be noted that a sensitive population (women who consume low iodide levels) has been identified (Blount et al., 2006), and this population was excluded from the study of Greer et al. (2002). An apparent additional iodide inhibitory effect was noted by Steinmaus et al. (2007) in women who smoke (and consume low iodine). We therefore recommend that either the BMDL of 3.7 ug/kg-day be utilized for the calculation, or that an extra 3-fold uncertainty factor be utilized in the EPA NOEL/UF approach to account for the missing sensitive subpopulation and to help account for the known variability.

Because the NRC panel did not have access to the data of Blount et al. (2006), relying on the NRC conclusions without specific acknowledgement that that approach does not address the sensitive population issues seems inappropriate.

Response: See response to comment ID 20641 under comment code 2100. EPA agrees with the commenter's suggestions regarding the review and evaluation of additional new data regarding the health effects of perchlorate, and will do so as part of the perchlorate regulatory process.

Comment: The EPA has set an official reference dose of .0007 mg/kg/day of perchlorate, which is not expected to cause adverse health effects in humans. The EPA then converted this reference dose into a drinking water equivalent level of 24.5 ppb by assuming a person weighs 154 pounds and consumes 68 ounces of drinking water per day over a lifetime. Based on these conversions, the drinking water equivalent level for infants should be 4.35 ppb. The EPA assumes that a perchlorate contamination level of 15 ppb is safe. However, this level more than triples the level assumed safe for infants.

Response: The NRC (2005) identified "the fetus of pregnant women who might have hypothyroidism or iodide deficiency" as "the most sensitive population," but also identified infants and developing children as additional "sensitive populations." Infants and young children have greater exposure to contaminants in food and water because of greater consumption of food and water on a per unit body weight basis. See response to comment code 5220 for a discussion of alternative Health Reference Levels. National Research Council (NRC). 2005. Health Implications of Perchlorate Ingestion. Comment: Compounding these problems, the CIIT relied heavily on a flawed, industry-funded study (the Greer study) when creating the computer model (Greer et al. 2002) - the problems with the Greer study have been documented in the published scientific literature and by the Massachusetts Department of Environmental Protection (Ginsberg and Rice 2005, MassDEP 2006).

Response: EPA believes that the Greer study, selected by the NRC as the basis for the RFD, represents the best available study for deriving a RfD. See response to comment code 2100.

EPA Comment ID: 20911
EPA Comment Code: 2100

Comment: The PBPK model relies heavily on industry-funded Greer study: The CIIT generated PBPK model uses data from the Greer study, which showed a dose-dependent decrease in iodine uptake (RAIU) by the thyroid gland with increasing perchlorate ingestion (Greer et al. 2002). This study included only 37 participants who were divided into several study groups and administered different doses of perchlorate for 14 days; the researchers determined that 0.007 mg/kg/day was the no observed effect level (NOEL) for perchlorate. The results from this study were used by the National Academy of Sciences (NAS) in setting the reference dose for perchlorate of 0.7 ug/kg/day.

However, the Greer study results and assumptions drawn from these results have been questioned in a peer-reviewed article that was published in Environmental Health Perspectives in 2005 (Ginsberg and Rice 2005). Two toxicologists, one from the Connecticut Department of Public Health and the other from the Maine Bureau of Health, conducted an analysis of the raw data from the Greer study and concluded that the "Individual results of Greer et al. point to an effect in four of the seven individuals tested at the lowest dose (0.007 mg/kg/day), indicating that this dose is an effect level." In other words, while Greer et al. and the NAS both concluded that 0.007 mg/kg/day is a NOEL, closer analysis of the data reveals that several of the 7 study subjects in this group experienced effects at this dose, thereby invalidating 0.007 mg/kg/day as a NOEL.

The Massachusetts Department of Environmental Protection (Mass DEP), which has set the most stringent drinking water standard for perchlorate nationally, had the following observations about the Greer study:

"MassDEP has concerns about the lowest dose in the Greer study being a no-effect level based on the facts that: due to the small number of subjects in the lowest dose group, there is low power to detect a statistically significant effect; averaging of group responses obscures positive individual inhibition; a non- statistically significant IUI (iodine uptake inhibition) effect was observed at the lowest dose tested; and, good low dose corroborating data is lacking" (MassDEP 2006).

In light of these valid criticisms of the Greer study, it is unclear why EPA chose to rely so heavily on the PBPK model that incorporates data from this study while essentially ignoring much more relevant data from the CDC.

Response: Blount et al., (2006) found that perchlorate exposure was a statistically significant predictor of thyroid hormones in women, but not in men. Their observations that adverse thyroid hormone effects were found in women whose urinary iodine was below 100 ug/L is suggestive of a partial study population iodine deficiency status. Blount et al. (2006) also noted several limitations of their study. Since their study was cross-sectional in design, it also cannot be concluded whether or not the association between perchlorate and thyroid hormone levels is causal, or is mediated by some other correlate of both. Blount et al., (2007) found that almost all participants in the same 2001-2002 NHANES survey, including the participants in their 2006 study, had urinary levels of perchlorate corresponding to estimated dose levels that are below the RfD of 0.7 ug/kg/day. The NRC recommended that data from the Greer et al. (2002) human clinical study be used as the basis for deriving a perchlorate reference dose (RfD) (NRC 2005), and also noted that the results of this study were supported by those of other human studies. From this Greer et al. (2002) human clinical study, the statistical no observed effect level (NOEL) for the perchlorate-induced inhibition of thyroid iodide uptake was determined to be 7.0 ug/kg (a corresponding iodide uptake inhibition of 1.8%). The NRC recommended that EPA apply an uncertainty factor of 10 to this NOEL of 7.0 ug/kg for the perchlorate-induced inhibition of thyroid iodide uptake, to account for differences in sensitivity between healthy adults and the most sensitive sub-population, consisting of fetuses of pregnant women who might have hypothyroidism or iodide deficiency.

EPA evaluated the published PBPK models (Clewell et al., 2007, and Merrill et al., 2005) and used them to further explore the relationship between water concentrations and iodide uptake inhibition in different subpopulations (USEPA, 2008). However, EPA did not rely on this PBPK analysis for determining the HRL. Rather, the HRL of 15 µg/l was calculated directly from the RfD to protect

the most sensitive subpopulation, the fetuses of pregnant women, using high end exposure assumptions. EPA thus applied the adjusted model to the HRL of 15 µg/l to determine the predicted percent RAIU inhibition (USEPA, 2008), and found that the 2.2 percent inhibition level for 7-day old bottle fed infants is comparable to the 1.8 percent inhibition level that the NRC identified as a no effect level in healthy adults and recommended as the point of departure for calculating the RfD (NRC, 2005). So, the modeling essentially agrees with the original NRC conclusions, and yielded results comparable to or below the 1.8 percent no effect inhibition level from the Greer (2002) study.

EPA used the best available peer-reviewed science, and the Agency has determined to regulate perchlorate in drinking water.

Comment: The EPA Reference Dose is not Adequately Protective of Human Health

The EPA Reference Dose is based on a Limited Study

The EPA Reference Dose for perchlorate is based on data from Greer et al. (2002) that observed the inhibition of radioiodide uptake. Ginsberg and Rice (2005) identified several problems with the Greer study that suggest the need for a reevaluation of the value that serves as the foundation for regulatory decision- making:

* Several individuals in the low dose group appear to demonstrate a response to perchlorate that is not evident in the reported mean. In analyzing this study, the National Academy of Sciences used the average response, and the significant variability in the response likely diminished the impact (e.g., as a result of reduced statistical power) of those showing a response.

* Ginsberg and Rice also point out that the apparent non-significant response resulted in the NAS characterizing the dose as a NOAEL, rather than a LOAEL. In their paper Ginsberg and Rice suggest an alternative interpretation that "[t]he data of Greer et al. (2002) point toward a more sensitive subgroup, which in this case represents more than half of the test group but is not evident

in the group mean analysis due to the variable nature of the response." If this is indeed the case then we can expect that there will be a wide range of susceptibility to perchlorate effects in the larger population.

Comment: 2. The very particular case of perchlorate: Total effective perchlorate NOEL and RfD

-These food and drinking water perchlorate background levels are now known also for the U.S. population.

-These food and drinking water perchlorate background level are very low

-Therefore adding the background perchlorate level to the Greer (nominal) NOEL does not significantly increase the effective NOEL (from 7.0 to 7.04 ug/kg-day)

-However what significantly increases the nominal NOEL is the also known equivalent perchlorate background level caused by nitrate and thiocyanate and which results in an effective perchlorate equivalent NOEL of 12.8 ug/kg-day instead of 7 ug/kg-day.

Response: EPA believes that the Greer study as designed and interpreted by the authors is the appropriate interpretation. Addition of a correction for other sources would significantly bias the results. This is especially true given that the measured change in RAIU was a change relative to the start of the study, not an uncorrected measure. The use of the start of study measure effectively corrected for any background levels that existed on a subject by subject basis. Also, see response to comment code 2100.

Comment: The NRC RfD on itself was based on the Greer et al., 2002(1) critical study.

NRC believed that the Greer study cohort that had been administered the perchlorate dose-response doses, was, in terms of competitive iodine uptake inhibition caused by perchlorate (and, we suppose, by goitrogens in general), representative for the adult US population excluding the more sensitive subpopulations (The RfD took into account these subpopulations by applying an uncertainty factor, UF).

Conversely if this cohort would not have been representative for this (general) segment of the US population, the Greer study outcome wouldn't have been so either and therefore the resulting RfD couldn't have been assumed to be health protective for the US population either.

To our knowledge no argument has emerged that put in doubt the representativeness of the Greer cohort.

Response: EPA agrees.

EPA Comment Code: 2100

Comment: The Greer study is a type 3 set-up (see section 1.3 below).

EPA asserts that it was applying a "default" RSC to estimate its former recommended DWEL (Drinking Water Equivalent Level) of 24.5 ppb issued in 2005 and based on the Greer study . With all due respect, EPA rather found that the RSC was not applicable for the reasons explained before. Indeed arriving at a 24.5 ppb DWEL from the RfD of 0.70ug/kg-day implies a RSC equal to 1 according to above equation with BW= 70 kg and DW =2l/day.

1.3. The Greer trial set-up

The Greer study cohort, in order to determine dose-response effects, received several oral doses of perchlorate.

Those doses were in addition to their background perchlorate levels originating from DW and food background sources.

The Greer trial was thus a type 3 set-up.

In fact the real NOEL for perchlorate alone (NOEL2) was not 0.7ug/kg-day as generally assumed but 0.7ug/kg-day plus the background from food + water. Thus in fact the 0.7ug/kg-day Greer NOEL (NOEL1) was an approximate or nominal level.

Establishing DW maximum contaminant levels based on trials where the contaminant is already consciously present in the background are not frequent but precedents do exist.

* The MCL of 2 ppm for barium was based on Wones R.G et al, Lack of Effect of Drinking Water Barium on Cardiovascular Risk Factors, Environmental Health Perspectives Volume 85, 1990, a critical human study, analogue to the Greer 2002.

We quote from Massachusetts Department of Environmental Protection:

http://www.mass.gov/dep/water/drinking/standards/barium.htm: "The MCLG is based on the RfD (presented below) derived from the Wones et al., study. It assumes that a 70 kg adult ingests 2

L/day of water. Since this value is based on a human study that considers contributions from food and air, no relative source contribution was applied for drinking water exposures"

* Also the nitrate MCL of 10 ppm N (as nitrate) was based on 2 critical human studies:

-Bosch H et al., (1950). Methemoglobinemia and Minnesota well supplies. Journal of the American Water Works Association 42:161-70, 1950 and

-Walton G (1951). Survey of literature relating to infant Methemoglobinemia due to nitrate contaminated water. Am. J. Public Health 41:986-96, 1951. There the RSC was considered as "not applicable" i.e. equal to 1.The RSC was not applicable because it did not have sense to apply it.

* The same reasoning went into the Cal. PHG (Public Health Goal) for fluorine: with an RSC = 100% followed by this

Comment: "OEHHA assumes that the populations under study exhibited comparable dietary and hygiene exposures to fluoride. Therefore, the relative source contribution factor is 100% to account for equal exposure of study populations to fluoride from sources other than drinking water (http://oehha.ca.gov/water/phg/pdf/fluor_c.pdf)

This is the same as saying that the study cohort was representative for the California population and that therefore the average background, which already contained fluorine, should have been so too.

Response: No response is necessary to the information provided by the commenter. Also, see response to comment code 2100.

Comment: B. The other goitrogens that are part of the background should be taken into account.

Most of the time, each contaminant has its own mode of action different from others or on different moments.

This is not the case for NIS (Sodium Iodine Symporter) related inhibitors of iodine uptake such as nitrate, perchlorate and thiocyanate which are competitive inhibitors with simultaneous joint effects (4).

Once again, to our knowledge this is the first time that background data are available also for the other goitrogens .This would allow to calculate an even more refined NOEL (NOEL4) and a corresponding HRL i.e. HRL4

In the Blount study those goitrogens were controlled for and evaluated when testing the relationship of perchlorate with T4 and TSH thyroid hormones. Average urinary(U) thiocyanate and nitrate levels were 1.2 (1.08-1.33 at 95% CI) and 38 mg/l (35.9-40.3 at 95% CI) respectively which, when

applying the relative potencies compared with perchlorate of 1/15 and 1/240(2) respectively, translated into 80 and 158 ug /L respectively.

80 ug /L U thiocyanate corresponds with about 2.8 ug/kg-day cyanide dietary uptake, applying the same regression as for perchlorate and assuming a 40% urinary recovery from cyanide and thioglucosides, the precursors of thiocyanate (5, 6).

158 ug /L U nitrate corresponds with about 3.0 ug/kg-day nitrate dietary uptake, applying the same regression as for perchlorate and assuming a 75 % urinary recovery (7, 8).

The total average perchlorate equivalent background is therefore estimated at 0.04 + 2.8 + 3.0 =5.8 ug/kg-day.

This comes down to trial set-up type 3 instead that the DW perchlorate BG plus the perchlorate equivalent BG should be added to the RfD and with RSC =1 since all contributors are now captured in the effective total equivalent NOEL (= NOEL4) and RfD (=RfD4) as shown in the following equations and fig.4 :

NOEL4= NOEL1 dose +FBG+ DWBG + PEBG.

RfD4= NOEL4/UF= NOEL4/10

HRL4 = [(RfD3 +PEBG) Ã— BW)/DWI] Ã— RSC= [(RfD4) Ã— BW)/DWI] x 1

Fig. 4: NOEL based on dose-response trial with perchlorate food background and with drinking water background: perchlorate equivalent background. [see PDF Docket ID EPA-HQ- OW-2008-0692-1798]

So the background levels of the other 2 goitrogens are substantially more relevant than the perchlorate back ground level itself.

This increases the effective perchlorate equivalent NOEL (NOEL4) to 7 ug/kg-day +5.8 ug/kg-day = 12.8 ug/kg-day which would have lead to a total goitrogen RfD4 of 1.28 ug/kg-day and a DW HRL4 of 44.8 ppb for perchlorate and nitrate/240 together (Thiocyanate in DW is negligible in the absence of a point source contamination).

Indeed when applying an RSC =1, BW= 70kg and DWI = 2 l/day, the HRL equation becomes:

HRL4 = [(RfD4 Ã— BW)/DWI] Ã— RSC = 44.8 ppb =45 ppb

So the perchlorate equivalent effect due to the other 2 goitrogens has a much larger impact on the final optimal HRL (HRL4) than the perchlorate background itself but has not been taken into consideration.

Response: While EPA acknowledges that nitrate and thiocyanate have the same mode of action as perchlorate, and that the effects of combined exposure to perchlorate, nitrate, and thiocyanate are additive, EPA does not believe there are sufficient scientific data currently available to assess and characterize the combined risk of these contaminants. EPA has committed to a drinking water

strategy that outlines four principles to expand public health protection for drinking water. One of these principles is to address contaminants as groups. However, EPA does not believe that regulatory action to address perchlorate should be further delayed. Therefore, EPA intends to develop a proposed rule for perchlorate. At such time as a NPDWR is promulgated, EPA is required to review and revise, as appropriate, its drinking water standards at least every six years. Any revision must at least maintain or improve public health protection. When there are sufficient scientific data to assess the cumulative risks of perchlorate and other contaminants, EPA will review this information to evaluate whether any new or revised NPDWRs are appropriate.

Comment: The NAS Study is the Most Comprehensive Scientific Review on the Health Effects of Perchlorate to Date.

We support EPA's decision to rely on the recommendations of the NAS perchlorate review panel in deriving a reference dose (RfD). From our perspective, the NAS panel conducted a thorough scientific inquiry of the available health effects literature in a highly professional and independent manner. The Panel's 2005 recommendations, based upon the best science then available, continue to be validated by new scientific studies on perchlorate health effects and exposures. It is critically important to bear in mind that the NAS panel views the perchlorate RfD as providing a large margin of safety because it is based on a No-Observed-Effect-Level (NOEL) as opposed to EPA's traditional approach of deriving the RfD from a No-Observed-Adverse-Effect-Level (NOAEL). The NOEL is a precursor effect (inhibition of iodine uptake by the thyroid) to an actual adverse effect (hypothyroidism). The RfD also incorporates a 10-fold safety factor to account for variability in the human population. For these reasons, the NAS views the RfD as highly health protective, even for sensitive subpopulations.

Response: See response to comment code 2100.

Comment: The RfD for perchlorate and perchlorate salts of 0.7 ug/kg body weight/day is based on a human volunteer study, Greer et al, 2002.[FN16: Greer, M.A., Goodman, G., Pleuss, R.C., Greer, S.E. 2002. Health effect assessment for environmental perchlorate contamination: The dose response for inhibition of thyroidal radioiodide uptake in humans. Environ. Health Perspect. 110:927-937.] The RfD is for oral exposure, including food and water, and is based on radioactive iodide uptake inhibition (RAIU) in the thyroid as the critical effect. The IRIS assessment of perchlorate explains that "The point of departure is based on a non-statistically significant mean 1.8% (standard error of the mean 8.3%) decline in RAIU in healthy adults following two weeks exposure to a daily perchlorate dose of 0.007 mg/kg/day. An intraspecies uncertainty factor of 10 is applied to protect the most sensitive population, the fetuses of pregnant women who might have hypothyroidism or iodide deficiency. Dose is given as perchlorate anion."[FN17: EPA. IRIS database. Perchlorate and perchlorate salts. http://www.epa.gov/ncea/iris/subst/1007.htm#revhis]

Comment: D. EPA relies on the RfD based on the comparatively weak Greer et al study to determine the HRL

In simple terms, the HRL is the maximum tolerable amount of perchlorate that could be in drinking water, considering that perchlorate is also in food, and still keep daily consumption levels from exceeding the RfD. The HRL was calculated as follows: For all populations, including pregnant women, EPA determined that the RfD is 0.7 ug/kg/day. This value is posted on the IRIS database based on recommendations from a committee of the National Academies. EPA reports that for pregnant women, exposure to perchlorate from food is 0.263 ug/kg/day at the 90th percentile (based on data from a national food survey), representing nearly 38% of the RfD, thus leaving an RSC (relative source contribution) for water of 62% (FR at 60276). This is equivalent to 0.437 ug/kg/day from water, assuming an average body weight of 70 kg, and a daily water consumption of 2 L (90th percentile adult water consumption). That is, 0.437 ug x 70 kg body wt. = 30.6 ug perchlorate in 2 L (the daily consumption amount). This is 15 ug/L, or 15 ppb, the HRL.

Because the dose-response relationship used to determine the RfD is derived exclusively from the Greer et al study, the HRL also is dependent on the Greer et al study to determine the maximum allowable level of drinking water contamination.

The Greer et al study [FN34: Greer MA, G Goodman, RC Pleus, and SE Greer. 2002. Health effects assessment for environmental perchlorate contamination: the dose- response for inhibition of thyroidal radioiodine uptake in humans. Environ Health Perspect 110:927-937.] reported on study results from intentional dosing of a small population (N=37) of healthy men and women, for only two weeks, and the study lacked measurements of iodine status that is now known to be a critical variable. Other serious problems with the Greer study included the fact that the low dose group contained only seven participants including only six women. Use of these limited data to calculate a regulatory trigger level has been widely criticized as inadequate by state scientific experts[FN35: Ginsberg G and D Rice. The NAS perchlorate review: questions remain about the perchlorate RfD. Environ Health Perspect. 2005 Sept; 113(9):1117-9. Erratum in: Environ Health Perspect. 2005 Nov; 113(11):A732.] and by EPA's own Children's Health Protection Advisory

Committee,[FN36: Letter from Melanie Marty to Administrator Johnson regarding Preliminary Regulatory Determination on Perchlorate (November 3, 2008, PDF) http://yosemite.epa.gov/ochp/ochpweb.nsf/content/perchlorateletter.htm/$file/PerchlorateLetter.pdf] and no longer reflects the best available data.[FN37: EN Pearce, AM. Leung, BC Blount, HR Bazrafshan, X He, S Pino, L Valentin-Blasini, and LE Braverman, 2007. Breast milk iodine and perchlorate concentrations in lactating Boston-area women. J Clin Endocrinol Metab. 92(5):1673-7.][FN38: Letter from Melanie Marty to Administrator Johnson regarding Preliminary Regulatory Determination on Perchlorate (November 3, 2008, PDF) http://yosemite.epa.gov/ochp/ochpweb.nsf/content/perchlorateletter.htm/$file/PerchlorateLetter.pdf] Despite these limitations, careful analysis of the Greer data reveal clear evidence of perchlorate toxicity in the low-dose group; three subjects showed no perchlorate effect, but four subjects in the low-dose group had a measurable decrease in iodide uptake commensurate with perchlorate exposure.[FN39: For a complete analysis of the NAS review of perchlorate, see: Ginsberg G and D Rice. The NAS perchlorate review: questions remain about the perchlorate RfD. Environ Health Perspect. 2005 Sept; 113(9):1117-9. Erratum in: Environ Health Perspect. 2005 Nov; 113(11):A732.] Because the study authors relied on averaged data rather than individual data, the more sensitive individuals in the study group were obscured

The short duration of the Greer study, only 14 days, creates considerable uncertainty that the cumulative effect of longer-term exposure are accounted for. A study in rats found greater perchlorate toxicity to the thyroid from 90- day exposure than from 14-day exposure (Springborn Laboratories 1998), suggesting that cumulative exposure may cause significant systemic injury that is not detectable in a short-term study. Although one longer-term (six month) human study with 13 volunteers has been promoted by industry as indicating that humans adapt to long-term exposure (Braverman et al. 2006[FN40: Braverman LE, EN Pearce, X He, S Pino, M Seeley, B Beck, B Magnani, BC Blount, and A Firek. 2006. Effects of six months of daily low-dose perchlorate exposure on thyroid function in healthy volunteers. J Clin Endocrinol Metab. Jul; 91(7):2721-4. Epub 2006 Apr 24.]) this study was unlikely to have adequate statistical power to detect an effect, especially given the particular vulnerability for some populations. The Blount (2006) study showed that some people are much more vulnerable to perchlorate toxicity than the average population; women are more sensitive than men, iodine-deficient women are more sensitive than iodine-sufficient women, and iodine-deficient women with TSH levels on the high end of the normal range are even more sensitive than other iodine-deficient women.[FN41: Blount BC, Pirkle JL, Osterloh JD, Valentin-Blasini L, Caldwell KL. Urinary perchlorate and thyroid hormone levels in adolescent and adult men and women living in the United States. Environ Health Perspect. 2006 Dec;114(12):1865-71.] Other human studies suffer from the same limitations. For example, a study of chronically perchlorate-exposed pregnant women in Chile[FN42: Tellez RT, PM Chacón, CR Abarca, BC Blount, CB Van Landingham, KS Crump and JP Gibbs. 2005. Long-term environmental exposure to perchlorate through drinking water and thyroid function during pregnancy and the neonatal period. Thyroid 15(9):963-975.] that also failed to find an effect of perchlorate exposure had only three iodine- deficient female subjects out of 183.

Response: Regarding this comment encouraging EPA to review additional data to support the perchlorate regulatory determination, EPA will continue to rely on the best available science as it proceeds through the rulemaking process.

Please see the response to comment ID 20987 under comment code 2100, and the response to comment code 2100 for a discussion of the RfD. Please see the response to comment code 5220 for a discussion of alternative Health Reference Levels.

Comment: EPA tries to support its conclusions that the HRL is safe by avoiding referring to the RfD, and instead referring to the level of inhibition of RAIU on which the NRC report (NRC, 2005) based its recommended RfD.[FN54: 73 Fed. Reg. at 60277.] EPA cannot pretend that its own RfD does not exist, and shift its evaluation of acceptable exposure estimates to a discrete biological endpoint.

Comment: 5. Your letter also raises concerns with the Greer et al. study, stating that the RfD is uncertain and not necessarily a health protective benchmark because Greer was a short-term study with a small sample size.

The NAS perchlorate panel addressed this very issue at length in their comprehensive report, pointing out that there were four doses across 37 subjects. Second, the panel concluded that since the point of departure is based upon IUI- a short-term event- any chronic effects "would have no greater effect" than any short term effects that may occur (NAS, 2005). Importantly, the NAS also noted that it did not examine Greer in isolation. The NAS noted that the findings in Greer are supported by other clinical studies, occupational and environmental epidemiological studies, and studies of long-term perchlorate administration to patients with hyperthyroidism. ATSDR reviewed all the literature in its 2008 toxicology document and still agrees that Greer et al. (2002) is the best study to determine a point of departure for a toxicity guideline value.

Comment: [Text Box: On basing an RfD on a no effect level for a non adverse effect, the NRC states: "Inhibition of iodide uptake by the thyroid clearly is not an adverse effect; however if it does not occur, there is no progression to adverse health effects."]

For this current regulatory determination, EPA has the benefit of a rigorous and independent peer review of the available science. These include the study by the NRC and more recently the Agency for Toxic Substances and Disease Registry, an agency of the Department of Human Health Services (ATSDR, 2008).

In 2005, the NRC perchlorate panel reached a consensus and recommended an RfD of 0.0007 mg/kg per day. The NRC panel comprised 15 leading scientists and physicians with wide-ranging expertise necessary to evaluate all aspects of the available science related to perchlorate. The NRC process occurred over a 15- month time period, providing ample time for the panel to review studies and consider oral testimony and written comments prior to issuing its conclusions and recommendations. As part of this process, the NRC panel performed an exhaustive review of the wide body of available animal and human studies as well as other scientific data relevant to understanding the health effects of perchlorate. The NRC panel noted that "emphasis was given to studies with the soundest scientific methods to draw conclusions regarding the effects of perchlorate exposure" (NRC, 2005).

The charge to the Committee was to "critically evaluate the scientific literature, including both human and animal data, and...assess the key studies underlying EPA's 2002 Draft Toxicological Review and Risk Characterization for Perchlorate in terms of quality, reliability, and relevance to draw conclusions about the health implications of exposure to low levels of perchlorate in drinking water." As stated in the NRC Committee Report, "EPA has been criticized that it did not appropriately consider all the relevant data for its assessments and that it based its conclusions on flawed scientific studies" (NRC, 2005).

The NRC independently evaluated the science which was published in the report Health Implications of Perchlorate Ingestion (2005). The NRC report recommended an RfD of 0.7 ug/kg-d based on a No Observed Effect Level (NOEL), or the dose at which no effects occur, adverse or otherwise (NRC, 2005). One of the critical studies that served as the basis for this RfD was the study by Greer et al. (2002) which demonstrated that there was no inhibition of iodide uptake by the thyroid at a dose of 7 ug/kg-d. Importantly, the NRC did not examine Greer in isolation. According to the NRC report, the findings in Greer are supported by other clinical studies, occupational and environmental epidemiologic studies, and studies of long-term perchlorate administration to patients with hyperthyroidism.

Further, the NRC states with emphasis, "Inhibition of iodide uptake by the thyroid clearly is not an adverse effect; however if it does not occur, there is no progression to adverse health effects." The committee views its recommendation to use [IUI] by the thyroid as the basis of the perchlorate risk assessment to be the most health-protective and scientifically valid approach (NRC, 2005).

[Text Box: After review all scientific data, including studies since the release of the NRC perchlorate review, ATSDR has adopted the EPA's chronic RfD recommended by the EPA (2005) for the chronic MRL"]

In using a NOEL, the NRC committee was conservative as this dose is already lower than any dose in which adverse effects occur; a safety factor of 10 is further applied to the already conservative NOEL to account for the most sensitive individuals in a population, in this case, hypothyroid or iodine- deficient pregnant women and their developing fetuses. The NRC panel stated that using a NOEL as the point of departure is a more conservative and health- protective approach than EPA's customary approach of using the adverse effect (NRC, 2005). Thus, for example, the use of IUI as a point of departure is a more cautious health protective approach than using changes in thyroid hormones (a precursor to possible adverse effects) or to some adverse effect such as hypothyroidism.

The panel also took time to differentiate between a NOAEL and a NOEL, finding that there was confusion between the two and stating that the NOAEL is based upon an adverse effect, whereas the NOEL is based upon a nonadverse effect (NRC, 2005). With the incorporation of an uncertainty factor of 10, the RfD recommended by the NRC was many times lower than the point at which adverse effects occur. It should be noted that the NRCNRC report concluded that no other uncertainty factors were necessary. Specifically on the issue of adequacy of database, the NRC concluded that the database contained sufficient studies from which to determine an RfD, finding that the database contained both human and animal data from which to evaluate IUI. The NRC also concluded that no LOAEL to NOAEL conversion factor was required, since the point of departure was the NOEL, again, a more conservative approach. Some have also argued that the Greer study was of short duration and have argued for a subchronic to chronic extrapolation. On that issue, the NRC concluded that since the point of departure is based upon IUI-a short-term event-any chronic effects "would have no greater effect" than any short term effects that may occur. (NRC, 2005).

The EPA has based its RfD for perchlorate and Integrated Risk Information System (IRIS) summary on the NRC report.

EPA Comment ID: 21059
EPA Comment Code: 2100

Comment: It should be noted that the RfD aims to protect the most sensitive individuals within a population (i.e., pregnant women and their fetuses). While some have argued that the infant or child is the more sensitive individual in the population; the experts of the Perchlorate NRC committee, EPA, ATSDR, OEHHA, and others, disagree. In addition, no reliable scientific data at relevant environmental exposures for this change in sensitive population has been put forward. One of the central considerations in these arguments is the disregard of dose and exposure. Any chemical at a sufficient dose will cause an adverse effect.

[Text Box: Studies published since the NRC report in 2005 add to an already well-developed database, adding more studies that are consistent to previous analyses and reducing uncertainty. Thus, the science supports EPA's decision that the current RfD for perchlorate is both conservative and health protective to even the most sensitive individuals.]

However, dose is a foundational tenant of the standard medical sciences (e.g., toxicology, endocrinology, pharmacology, etc.). Dose consideration is an absolute foundation of the risk assessment process by all recognized authoritative bodies.

Response: See response to comment code 2100.

EPA Comment Code: 2100

Comment: First, as stated above, ATSDR (2008) reviewed this study in their assessment and did not feel that it merited any special consideration over other studies in the well developed perchlorate literature database. They state that their decision "...was made after a careful evaluation of the NRC report and of studies that have been published after the NRC (2005) report. The results from newer studies do not change the bottom-line recommendation" (ATSDR, 2008).

Response: No response is necessary to the information provided by the commenter.

EPA Comment Code: 2100

Comment: EPA has provided sufficient support for its findings under the SDWA. To take the statutory criteria in turn:

May perchlorate have an adverse effect on the health of persons?

Everything - including water itself - may cause an adverse effect if the dose is sufficiently high. The plain meaning of the first criterion relates to the dose of the contaminant at levels which people are likely to be exposed to through drinking water.

The scientific literature is clear that perchlorate will not cause adverse effects at the concentrations under review here. The NAS report declares,

An important point is that inhibition of thyroid iodide uptake is the only effect that has been consistently documented in humans exposed to perchlorate. The continuum of possible effects of iodide-uptake inhibition caused by perchlorate exposure is only proposed and has not been demonstrated in humans (with the exception that in patients with hyperthyroidism doses of 200 mg daily or higher may reduce thyroid secretion). More importantly, the outcomes at the end of the continuum are not inevitable consequences of thyroid exposure.

In other words, except for its deliberate medical use, perchlorate has never been shown to have caused adverse effects in humans. Moreover, the NAS also concluded that perchlorate is not likely to be a carcinogen.

In addition to the NAS conclusions, subsequent studies indicate perchlorate has not been demonstrated to have an adverse effect on the health of persons at environmentally relevant levels (Blount et al., 2006). The weight-of-evidence suggests that adverse effects do not occur following chronic exposures to perchlorate at doses much greater than the RfD (Tellez et al., 2005; Amitai et al., 2006; Braverman et al., 2006).

Response: EPA's final determination to regulate perchlorate is based upon the National Research Council's 2005 (NRC, 2005) recommendation to use data from a human clinical study (Greer et al. 2002) as a basis for the human health risk assessment, and as a basis for the RfD. On August 19, 2009, EPA published a FR Notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (FR Vol. 74, No. 159, p. 41883). In this August 19, 2009 FR Notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard. EPA has considered and discusses in the FR Notice the results of current scientific literature on potential adverse biochemical effects, in the process of evaluating the adverse human health effects of perchlorate. See response to comment code 2100.

Comment: November 21, 2008 Water Docket Environmental Protection Agency Mailcode 2822T 1200 Pennsylvania Ave, NW Washington DC 20460 Re: Docket 1D No. EPA-HQ-OW-2008-0692

The Connecticut Department of Public Health appreciates this opportunity to comment on the Agency's Preliminary Regulatory Determination for Perchlorate dated Oct 10, 2008. We have been following perchlorate closely because of its toxic properties and widespread occurrence in the human environment, particularly in food and water supplies impacted by local sources. It appears that risks from perchlorate in drinking water could be appreciable during the perinatal period in cases where iodine intake is marginal. This concern comes from the CDC study showing that perchlorate body burden is correlated with decreased thyroid hormone levels in the 31% of US women with low iodide intake (Blount et al. Environ Health Perspect 114:1865, 2006). Given the sensitive relationship between thyroid hormone and brain development, it is critical that the perinatal period be adequately protected from agents which can interfere with thyroid hormone

production. Therefore, regulting perchlorate in drinking water represents a meaningful opportunity for EPA to safeguard public health by setting a health-protective Maximum Contaminant Level (MCL) and then by requiring water supplies to regularly rest for this analyte.

Dear Sirs,

I appreciate the opportunity to comment on the United States Environmental Protection Agency (U.S. EPA) Office Water regarding its request for supplemental comments. I have been very active with the perchlorate issue over the past 11 years.

John P. Gibbs, MD PO Box 2948, 300 Fischer Store Road Wimberley, Texas 78676 Phone: 512-847-2748, cell 512-667-0625 Email: jpgibbs@hughes.net

1) The 2005 NAS REPORT

Perchlorate is one of the most well-studied chemicals with detailed information on the mechanism of action, dose-response, and health effects. The 2005 NAS report was a comprehensive review of the science. The animal and human studies that have been published since the NAS report reduce the uncertainty and reinforce the NAS panel's finding that there will not be any adverse health effects from perchlorate at environmentally-relevant concentrations

In using a NOEL, the NAS committee deemed its approach as conservative and health protective as this dose is already lower than any dose in which adverse effects occur. Furthermore, a safety factor of 10 is applied to the NOEL to account for the most sensitive individuals in a population, in this case, hypothyroid or iodine-deficient pregnant women and their developing fetuses. The NAS panel stated that "the NOEL value from Greer et al. (2002) is a health- protective and conservative point of departure is supported by...extensive human and animal data that demonstrate that there will be no progression to adverse effects if no inhibition of iodide uptake occurs"

Response: For the reasons provided in the preliminary and final determinations, EPA has found that perchlorate may have an adverse effect on human health. Also, see response to comment code 2100.

Comment: 5) CONCLUSIONS

The 2005 NAS report remains the most credible and complete assessment on potential toxicity of perchlorate from environmental sources. All scientific reports issued after the NAS report (with the exception of Blount et al 2006) support that the RfD recommended by the NAS is protective for sensitive subpopulations. Setting an MCL for perchlorate in drinking water below 15 or 24 ug/L does not provide meaningful opportunity for improving public health.

Response: EPA has considered the results of current scientific literature on potential adverse biological effects, in the process of evaluating the adverse human health effects of perchlorate. The Agency analyzed the additional information, and EPA has determined that a national primary drinking water regulation for perchlorate would present a meaningful opportunity for health risk reduction for persons served by public water systems, and that regulation of perchlorate in drinking water due to occurrence and health implications is warranted. EPA will continue to evaluate all of the available science related to perchlorate as the Agency develops a National Primary Drinking Water Regulation for perchlorate. See response to comment code 5220 for a discussion of alternative Health Reference Levels.

Comment: The NAS Report Remains the Most Comprehensive Scientific Review on the Health Effects of Perchlorate to Date.

The National Academy of Sciences conducted a thorough inquiry of the perchlorate health effects literature in a highly professional and independent manner. The Panel's 2005 recommendations, based upon the best science available, continue to be validated by new scientific studies on perchlorate health effects and exposures. It is critically important to bear in mind that the NAS panel views its recommended perchlorate reference dose (RfD) as providing a large margin of safety because it is based on a No-Observed-Effect-Level (NOEL) -- inhibition of iodine uptake by the thyroid - rather than the traditional approach of starting from a No-Observed-Adverse-Effect-Level (NOAEL). The NOEL is the level below which exposure to a substance fails to elicit any biological response at all, and in the case of perchlorate is orders of magnitude below the levels at which

adverse effects may occur. The NAS perchlorate panel further reduced this NOEL by a factor of 10 to account for variations in human response, leading them to conclude that their recommended RfD is highly health protective, even for sensitive subpopulations.

Further downward adjustment of the RfD based on body weight and water consumption rates at various life stages, as contemplated in EPA's proposed alternative health reference levels, is needlessly duplicative and provides no additional health protection for any population. Moreover, EPA has not presented any scientific evidence indicating why its current perchlorate health reference level (15 ppb), which is based on the most sensitive sub-population (the pregnant woman/fetus), and which incorporates a ten-fold safety factor to account for variability in human response, is inadequate.

Response: See response to comment code 5220 for a discussion of alternative Health Reference Levels.

EPA Comment Code: 2100

Comment: The NRC perchlorate panel (2005) and the EPA agreed that the most susceptible population are "the fetuses of pregnant women who might have hypothyroidism or iodide deficiency" but also identified infants and developing children as additional "sensitive populations." Epidemiological data shows that at perchlorate exposures above and below the EPA's Reference Dose (RfD) for perchlorate, no adverse health effects were documented in adults and children exposed chronically to perchlorate via drinking water (Crump and Gibbs 2005; Tellez, Chacon et al. 2005; Amitai, Winston et al. 2007).

Response: See response to comment code 2100 and today's Federal Register notice for a discussion of EPA's finding of possible adverse health effects.

Comment: Second, EPA must make it clear to the public that the starting point for determining the Reference Dose (RfD), a safe daily exposure level for perchlorate, is a biological effect that is not itself harmful, and does not indicate any harm will occur. In 2005, an expert panel of the National Research Council (NRC) reviewed the evidence and determined a reference dose (RfD) for perchlorate based on a No Observed Effect Level (NOEL) in a study in human subjects. The NOEL is the lowest observed dose at which no biologically significant changes are observed, and it is a lower does than the customary starting point for an RfD, the No Observed Adverse Effect Level (NOAEL), the dose at which no adverse effects are observed. Humans and animals have built-in, compensatory mechanisms that assure their survival over a wide range of complex and continually changing challenges. Biological changes that are part of these normal compensatory

mechanisms are considered adaptive, not adverse. The NRC experts specifically articulated that extra measure of protection inherent in their use of the NOEL. In addition, they used a safety factor of 10 to account for any variations in sensitivity within the population potentially at risk, hypothyroid or iodine deficient pregnant women and developing fetuses. The NRC approach assures that, even if the sensitive population were to experience an exposure as high as the RfD there is a high degree of confidence that no adverse effects will occur.

Response: EPA believes the NRC appropriately based the RfD on iodide uptake inhibition to the thyroid, for the reasons discussed in its report. EPA notes that the data underlying the definition of iodide uptake inhibition as a precursor effect and the relationship of iodide uptake inhibition to the continuum of adverse outcomes reflects an understanding of effects in adults; it may not reflect the relationship of the precursor event to adverse outcomes in neonates and infants, who may not have iodide stores sufficient to offset the effects of reduced iodide uptake. The less resilient neonatal and infant system makes the exposure gap between a precursor event (iodide uptake inhibition due to perchlorate) and reduced T3/T4 levels likely to be narrower than for adults, and in fact, the distinction between the two may be blurred for the very young (Greer et al., 2002; Savin et al., 2003; van den Hove et al., 1999). The NRC noted that, "[T]he minimal prolonged decrease in thyroid hormone production that would be associated with adverse health effects is not known; any decrease is potentially more likely to have adverse effects in sensitive populations (people with thyroid disorders, pregnant women, fetuses, and infants) but data are not available to determine the magnitude of the decrease needed to cause adverse effects in those populations."

Comment: Moreover, a 1 ppb or lower MCL is supported by the most recent comprehensive studies, and these should be central to EPA's analysis. The industry-supported Greer study, which serves as the basis for EPA's current reference dose as well as California's current 6 ppb standard, consisted of a 14-day study of 37 healthy adults. In more recent years, Blount et al analyzed a nationally representative sample of 2299 U.S. residents, and they have documented anti- thyroid effects in a large population of women exposed to perchlorate at concentrations far lower than levels previously shown to have such effects. This study and subsequent data clearly justify promulgation of an even more protective MCL. It should be noted that California's Office of Environmental Health Hazard Assessment is in the process of reevaluating its Public Health Goal, on which the state MCL is based.

Response: See response to comment code 5220 for a discussion of alternative Health Reference Levels and response to comment code ID 28936 under comment code 2100 for a discussion of the Blount et al study. EPA will conduct further analysis in developing a proposed MCL and MCLG for perchlorate.

Comment: A reference dose (RfD) is an estimate of the daily exposure to an agent over a full lifetime that is "likely to be without an appreciable risk of deleterious effects" for the human population, including sensitive subgroups.[FN13: EPA Integrated Risk Information System (IRIS) Glossary of terms. http://www.epa.gov/ncea/iris/help_gloss.htm#r] The RfD is not an enforceable regulatory standard; it can be used with exposure information to set clean up levels. In 2005, the National Research Council (NRC) of the National Academies of Science recommended an RfD for daily intake of perchlorate that it considered to be an acceptable level of exposure of 0.7 ug/kg/day.[FN14: NRC. 2005. Health Implications of Perchlorate Ingestion. National Research Council of the National Academies. National Academies Press, Washington, D.C.] EPA adopted this RfD and posted on its public database, the Integrated Risk Information System (IRIS) in February 2005.[FN15: EPA IRIS assessment of perchlorate. http://www.epa.gov/NCEA/iris/subst/1007.htm] While IRIS values are not regulations per se, they are used by both state and federal regulators and by the international community for a range of environmental health regulation and management purposes. For example, the information can be used in combination with exposure data to set cleanup levels at hazardous waste sites, or to set exposure standards for air, water, soil, and food. Thus, the accuracy, credibility, and timeliness of IRIS assessments have real world consequences for human health.

In simple terms, the HRL is the maximum contamination level of perchlorate that could be in drinking water, and still keep daily human consumption levels from exceeding the RfD of 0.7 ug/kg/day. It is not an enforceable standard. EPA reports that for pregnant women, exposure to perchlorate from food is 0.263 ug/kg/day at the 90th percentile (based on data from a national food survey), representing nearly 38% of the RfD, thus leaving an RSC (Relative Source Contribution) for water of 62%.[FN16: 73 Fed Reg at 60276] This is equivalent to 0.437 ug/kg/day from water, assuming an average body weight of 70 kg, and a daily water consumption of 2 L (90th percentile adult water consumption). That is, 0.437 ug x 70 kg body wt. = 30.6 ug perchlorate in 2 liters (the daily consumption amount). This is 15 ug/L, or 15 ppb, the originally proposed HRL.

The RfD for perchlorate and perchlorate salts of 0.7 ug/kg body weight/day is based on a human volunteer study, Greer et al, 2002.[FN17: Greer, M.A., Goodman, G., Pleuss, R.C., Greer, S.E. 2002. Health effect assessment for environmental perchlorate contamination: The dose response for inhibition of thyroidal radioiodide uptake in humans. Environ. Health Perspect. 110:927-937. Docket HQ- OW-2009-0297 NRDC supplemental comments on perchlorate] The RfD is for oral exposure, including food and water, and is based on radioactive iodide uptake inhibition (RAIU) in the thyroid as the critical effect. The IRIS assessment of perchlorate explains that "The point of departure is based on a non- statistically significant mean 1.8% (standard error of the mean 8.3%) decline in RAIU in healthy adults following two weeks exposure to a daily perchlorate dose of 0.7 ug/kg/day. An intraspecies uncertainty factor of 10 is applied to protect the most sensitive population, the fetuses of pregnant women who might have hypothyroidism or iodide deficiency. Dose is given as perchlorate anion."[FN18: EPA. IRIS database. Perchlorate and perchlorate salts. http://www.epa.gov/ncea/iris/subst/1007.htm#revhis]

The RfD adopted by EPA has been widely criticized as inadequately protective by state scientific experts[FN19: Ginsberg G and D Rice. The NAS perchlorate review: questions remain about the perchlorate RfD. Environ Health Perspect. 2005 Sept; 113(9):1117-9. Erratum in: Environ Health Perspect. 2005 Nov; 113(11):A732.] and by EPA's own Children's Health Protection Advisory

Committee,[FN20: Letter from Melanie Marty to Administrator Johnson regarding Preliminary Regulatory Determination on Perchlorate (November 3, 2008, PDF) http://yosemite.epa.gov/ochp/ochpweb.nsf/content/perchlorateletter.htm/$file/PerchlorateLetter.pdf] and no longer reflects the best available data.[FN21: EN Pearce, AM. Executive Summary

In evaluating the risks posed by perchlorate and the value of regulation through establishment of an MCL, EPA is relying on information derived from a flawed analysis of the impacts of perchlorate exposure. There are two primary factors that have significantly impacted the perchlorate risk assessment, and could explain the omissions and contradictions mentioned further below.

First, the NOEL (Non Observed Effect Level) found in the Greer 2002 study from which the perchlorate RfD is derived, did not take into account existing background effect. The root of this omission could lie in the fact that a qualitative observational study, which takes into account background levels and is by far the most common human epidemiological study used in evaluating exposure risks to humans, was not performed or relied on in analyzing the impact of perchlorate in this instance. Instead, the Greer study was an experimental study on humans, which did not take into account background effects and thus significantly overstates the impact of perchlorate on human health. Therefore, the NOEL found by the Greer study is not accurate, and should not be relied upon to either regulate perchlorate or establish an RfD.

Response: EPA respectfully disagrees with the commenter. The RfD, which is derived from the NOEL, is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population that is likely to be without an appreciable risk of deleterious effects during a lifetime. The RfD, based on the assumption that thresholds exist for certain toxic effects of chemicals, represents the drinking water perchlorate exposure plus an incremental additional exposure of perchlorate from either water or food which could trigger iodine uptake inhibition, with a 10X safety factor applied. The NRC recommended that data from the Greer et al. (2002) human clinical study be used as the basis for deriving a perchlorate reference dose (RfD) (NRC 2005), and also noted that the results of this study were supported by those of other human studies. From this Greer et al. (2002) human clinical study, the statistical no observed effect level (NOEL) for the perchlorate-induced inhibition of thyroid iodide uptake was determined to be 7.0 ug/kg (a corresponding iodide uptake inhibition of 1.8%). The NRC concluded that the most health protective and scientifically valid approach to deriving a reference dose for perchlorate was to base the perchlorate RfD on the precursor event of inhibition of iodide uptake by the thyroid, which would precede any more severe adverse health effects of perchlorate exposure in humans. In this case, the NRC used a precursor to adverse thyroid effects to establish a level at which no adverse effects would be anticipated in exposed populations. This approach is consistent with the Agency's policy on the use of precursor events when appropriate in establishing the critical effect upon which an RfD is based (U.S. EPA, 2002). The NRC recommended that EPA apply an uncertainty factor of 10 to this NOEL of 7.0 ug/kg for the perchlorate-induced inhibition of thyroid iodide uptake, to account for differences in sensitivity between healthy adults and the most sensitive sub-population (fetuses of pregnant women who might have hypothyroidism or iodide deficiency). The NRC viewed the recommended uncertainty factor of 10 as conservative and protective of health, given that the NOEL is based on a non-adverse effect (iodide uptake inhibition). NRC recommended that using a non-adverse effect that is upstream of the adverse effect represents a more conservative, health-protective approach to the risk assessment for perchlorate, noting that the purpose of the 10-fold uncertainty factor is to protect sensitive subpopulations in the face of uncertainty regarding their relative sensitivity to perchlorate exposure. EPA has adopted the NRC's recommendations in its "Integrated Risk Information System" (USEPA, 2005), resulting in an RfD of 0.7 ug/kg/day, which was derived by applying a 10-fold uncertainty factor to the NOEL of 7.0 ug/kg/day. EPA used the best available peer-reviewed science, and the Agency has determined to regulate perchlorate in drinking water. EPA will continue to evaluate scientific studies of perchlorate health effects as part of the perchlorate rulemaking process. Greer MA, Goodman G, Pleus RC, Greer SE. Comment: 1.1. Introduction

The perchlorate NAS (National Academy of Sciences) RfD (Reference Dose) of 0.7ug//kg-day is based on the Greer 2002 dose response experimental clinical study[FN1: Greer MA, Goodman G, Pleus RC, Greer SE, 2002. Health Effects Assessment for Environmental Perchlorate Contamination: The Dose Response for Inhibition of Thyroidal Radioiodine Uptake in Humans. Environ. Health Perspective, 110(9):927-937.]. However the NOEL (Non Observed Effect Level) found in the Greer experimental longitudinal study did not take into account existing background effects, and therefore the Greer NOEL is not an accurate reflection of the NOEL for perchlorate.

NAS did not add this background level to the Greer NOEL level in its evaluation of perchlorate. Similarly, EPA's OIG did not do so in its December 2008 study [FN2: Office of Inspector General Scientific Analysis of Perchlorate, Assignment No. 2008-0010, December 30, 2008.]. The consequences of this omission are significant as discussed below.

Commenter Organization: Intertox, Inc.
EPA Document ID: EPA-HQ-OW-2009-0297-0662
EPA Comment ID: 28896
EPA Comment Code: 2100

Comment: As a reminder, Intertox provided comments to these studies in a 2008 submission; these comments are located in the EPA docket (Intertox, 2008). Intertox also provided comments to the Draft OIG report (Intertox, 2009). Nonetheless, these studies are summarized below. EPA has also posted several additional documents to the docket that require additional context.

A. The 2009 FR Notice Docket

The EPA Docket for this Notice (Docket ID No. EPA-HQ-OW-2009-0297) includes a number of documents including a commentary that provides criticism of the NRC expert panel's conclusions on perchlorate, but does not provide new scientific data from which to base a regulatory determination (Ginsberg and Rice, 2005). To provide a transparent compendium of available information, if the Agency provides or uses any commentaries, it should consider all commentaries. For example, a response to Ginsberg and Rice (2005) was published in the same journal. This response was co-authored by the NRC perchlorate panel chair and three other members from the 18-member panel and provides point-by-point science based rebuttals to why the Ginsberg and Rice (2005) assertions are incorrect. The response authors conclude by stating that the NRC-recommended RfD "provides a wide margin of safety for all subjects of all ages" (Johnston, et al., 2005). We request that EPA add this response to the docket.

Response: EPA will continue to evaluate the best available science related to perchlorate as the Agency develops a National Primary Drinking Water Regulation for perchlorate. The Johnson, et. al., commentary has been reviewed by EPA and added to the docket. Also, see response to comment code 2100.

Comment: Greer et al. (2002)

As noted above and briefly reiterated here, the mechanism of action (MOA) of perchlorate in humans is the inhibition of iodide uptake (IUI). The MOA has been reviewed by numerous authoritative bodies (NRC, EPA, ATSDR, etc.) who have concluded that it is not adverse. Iodide uptake is mediated by the NIS in the thyroid follicular cell. Greer et al. found a level where there was no statistical change in IUI and therefore, no downstream effects were possible.

That IUI is not adverse has been well-documented by NRC, EPA, New Jersey, California, and ATSDR. Much is documented about exposures to perchlorate at environmentally relevant doses up to therapeutic doses, the amount of IUI these doses cause, and the lack of downstream effects with environmentally relevant doses. For example, many studies demonstrate a statistically significant IUI, but no change in thyroid hormones for weeks or months (Greer et al., 2002; Braverman et al., 2005; Lawrence et al., 2000 and 2001; etc.). Moreover, the literature regarding perchlorate at therapeutic doses demonstrates the effect of IUI and changes in hormones. The NRC committee members unanimously stated that transient changes in thyroid hormones are not adverse and prolonged changes in thyroid hormones must occur for a person to become hypothyroid.

Some have argued that the study population of the Greer Study was too small to exhibit statistical significance of small changes in IUI particularly with the variability reported. It is important to note that decisions regarding statistical power and sample size were conducted a priori, in accordance with standard experimental design. These were stated and agreed upon by the researchers and EPA. The questions by some about variability have been raised a posteriori, after the results are known. Based on all the information available when the experiment was designed, the sample sizes in the Greer Study were sufficient. Notably, with a dose of 0.02 mg/kg-d, a 16% IUI (24-hr value) was statistically significant.

Regarding the variability of the low dose group, IUI from "background" (as noted above in Figure 3) perchlorate, nitrate, thiocyanate, and other agents found in the diet and drinking water were not controlled. This likely explains a significant proportion of daily interpersonal RAIU changes. Furthermore, 1) variability in RAIU for the low dose group was not different from RAIU for other dose groups, 2) all volunteers had normal baseline RAIU values when compared to the literature, and 3) when baseline RAIU is low, small absolute changes will appear large as relative RAIU, which is a mathematical, not physiologic, phenomenon.

In a dose-response study, one dose group should not be taken in isolation. The best way to evaluate the low-dose variability in RAIU is to examine all data generated by the study. Simple inspection of the data show a decrease in RAIU change with increasing dose-IUI occurred in a classic and unequivocal dose- response manner. Additionally, the No Effect Level (NEL) using linear regression of all relevant RAIU clinical data was 6 ug/kg-d for 24 hours, which was similar the NOEL of 7 ug/kg-d. Considering the data from Lawrence et al. (2001) which demonstrated a higher dose of perchlorate (approximately 40 ug/kg-d assuming 3 mg/d for a 70 kg person) with a non-statistically significant decrease in RAIU (as well as no corresponding change in thyroid hormones) strengthens this understanding.

Response: See response to comment code 2100. EPA will continue to evaluate all of the available science related to perchlorate as the Agency develops a National Primary Drinking Water Regulation for perchlorate.

Commenter Name: Anila Jacob
Commenter Organization: Environmental Working Group (EWG)
EPA Document ID: EPA-HQ-OW-2009-0297-0499
EPA Comment ID: 28936
EPA Comment Code: 2100

Comment: EWG urges the agency to take the results from this CDC study into account and revise the current RfD to reflect these findings. In written responses to questions for the record from the House Committee on Energy and Commerce dated from 2007 (attached), Dr. James Pirkle, Deputy Director for Science at the National Center for Environmental Health and coauthor of the study, had the following comments regarding the study results: "We do not think confirmatory analysis is necessary to validate Blount's analysis of the NHANES data. Although we understand that conclusions of causality can rarely be drawn based upon a single study, when viewed within the context of the available clinical literature, the findings of the Blount study are consistent with causality" (Attached). In addition, an independent analysis of the NHANES data by scientists who work for California's Office of Environmental Health Hazard Assessment confirmed CDC's findings (Steinmaus et al 2007). Given the issues with the data in the Greer study and the strengths of the Blount study, the agency should place greater weight on the results from the Blount study in its determination.

Response: In the October 10, 2008 FR Notice requesting public comments on its preliminary determination not to regulate perchlorate in drinking water (FR Vol. 73, No. 198, p. 60266), EPA considered and discusses the results of the Greer et al. (2002), and Blount et al. (2006, 2007) studies, in the process of evaluating the adverse health effects of perchlorate. Blount et al., (2006) published a study in the journal "Environmental Health Perspectives" examining the relationship between urinary levels of perchlorate and blood serum levels of TSH and total T4 in 2,299 men and women (ages 12 years and older) who participated in CDC's 2001–2002 NHANES. Blount et al. (2006) evaluated perchlorate along with a number of covariates known or likely to be associated with thyroid hormone levels, to assess the relationship between perchlorate and these hormones. The Blount et al. (2006) study found that perchlorate exposure was a statistically significant predictor of thyroid hormones in women, but not in men. For women with urinary iodide levels less than 100 ug/L, the researchers found that urinary perchlorate was associated with a decrease in T4 levels and an increase in TSH levels. For women with urinary iodide levels greater than or equal to 100 ug/L, the researchers found that perchlorate was a significant positive predictor of TSH, but not a predictor of T4. Their observations that adverse thyroid hormone effects were found in women whose urinary iodine was below 100 ug/L is suggestive of a partial study population iodine deficiency status. Blount et al. (2006) noted several limitations of their study and recommended that their findings be affirmed in other large studies focusing on women with low urine iodide levels. Since their study was cross-sectional in design, it also cannot be concluded whether or not the association between perchlorate and thyroid hormone levels is causal, or is mediated by some other correlate of both, although the relationship between urine perchlorate and total TSH and T4 levels persisted after statistical adjustments for some additional covariates known to predict thyroid hormone levels. EPA has evaluated this data as part of the regulatory determination EPA will

continue to evaluate new scientific information on the health effects of perchlorate as the Agency develops the proposed perchlorate drinking water regulation.

Commenter Name: Michael Girard
Commenter Organization: Perchlorate Study Group
EPA Document ID: EPA-HQ-OW-2008-0692-1855
EPA Comment ID: 29079
EPA Comment Code: 2100

Comment: EPA's preliminary determination includes imprecise language that bears clarification:

Perchlorate interacts with the sodium iodide symporter, reducing iodine uptake into the thyroid gland and, at sufficiently high doses, the amount of T4 produced and available for release into circulation. Sustained changes in thyroid hormone secretion can result in hypothyroidism. (p. 60275; emphasis added)

[Text Box: The NAS concluded that perchlorate will not cause adverse effects under consideration in this determination. The NAS findings are consistent, as well as the overwhelming majority of the large body of available peer-reviewed science on perchlorate.]

The "sufficiently high doses" that EPA refers to are orders of magnitude higher, approximately 0.4 mg/kg-d (approximately 19,000 ppb)[FN2: See, NAS, at 171-172 (pdf version) ("...a sustained exposure at more than 0.4 mg/kg per day would most likely be required to cause a sufficience decline in iodide uptake and thyroid hormone production to result in adverse health effects in normal adults. That estimate is based on clinical studies and studies of long-term treatment of patients who had hyperthyroidism.]. These levels have never been reported in public drinking water systems. According to the NAS report, even these levels do not inevitably lead to adverse effects.

The NAS independently evaluated the science and its conclusions and recommendations are published in the report Health Implications of Perchlorate Ingestion (2005). The NAS report recommended an RfD of 0.7 ug/kg-d based on a No Observed Effect Level (NOEL), or the dose at which no effects occur, adverse or otherwise (NAS, 2005). One of the critical studies that served as the basis for this RfD was the study by Greer et al. (2002) which demonstrated that there was no inhibition of iodide uptake by the thyroid at a dose of 7 ug/kg-d. Some have argued that the low dose group contained only seven subjects; however the NAS correctly dismissed this assertion, pointing out that there were four doses provided across 37 subjects. Importantly, the NAS also

noted that it did not examine Greer in isolation. According to the NAS report, the findings in Greer are supported by other clinical studies, occupational and environmental epidemiologic studies, and studies of long-term perchlorate administration to patients with hyperthyroidism.

Further, the NAS states with emphasis,

"Inhibition of iodide uptake by the thyroid clearly is not an adverse effect; however if it does not occur, there is no progression to adverse health effects." The committee views its recommendation to use [IUI] by the thyroid as the basis of the perchlorate risk assessment to be the most health-protective and scientifically valid approach (NAS, 2005).

In using a NOEL, the NAS committee adopted a notably conservative, health- protective approach. This dose is already lower than any dose in which adverse effects occur; an additional safety factor of 10 is applied to the already conservative NOEL. The NAS was acting to ensure protection for the most sensitive individuals in a population, in this case, hypothyroid or iodine- deficient pregnant women and their developing fetuses. Importantly, the NAS panel did consider other sensitive populations besides pregnant women and their fetuses. They also considered the potential effect on infants, developing children, people who have compromised thyroid function, and people who are iodide-deficient. The NAS panel stated that using a NOEL as the point of departure is a more conservative and health-protective approach than EPA's customary approach of using the adverse effect (NAS, 2005).

The NAS panel also took time to distinguish between a No Observable Adverse Effect Level (NOAEL) from a NOEL. The experts observed that there was confusion between the two and clarified that the NOAEL is based upon an adverse effect, whereas the NOEL is based upon a dose at which no effect occurs, adverse or otherwise. (NAS, 2005).

EPA adopted the RfD recommended by the NAS and confirmed that it was conservatively based on the NOEL, not the NOAEL. EPA should clarify its finding as to the potential adverse effects of perchlorate to bring the final determination into alignment with its own NAS-based reference dose.

In sum: perchlorate will not cause adverse effects at levels under consideration in this determination. This conclusion reflects the best available scientific findings, including the NAS report and the overwhelming majority of the large body of available peer-reviewed science on perchlorate.

EPA Comment Code: 2110

Comment: Our primary concerns relate to the current EPA RfD of 0.0007 mg/kg-day found on EPA's Integrated Risk Information System (IRIS), since new data have shown this value to be out of date.

Concern: EPA acknowledges in its Federal Register notice that critically important data on pregnant women and their offspring have become available since the time of the development of the EPA RfD in 2005 (EPA, 2008), but then fails to cite a prospective epidemiology study by Tellez et al. (2005) that analyzed the results of differing perchlorate exposures in pregnant mothers and their newborns. As a basis of an RfD, Tellez et al. (2005) is superior to the study used as the basis of the current RfD, that is Greer et al. (2002), since the Tellez et al. (2005) study is on the sensitive populations of interest (pregnant women and their babies). As a basis of an RfD, Tellez et al. (2005) is vastly superior to the ecological epidemiology study of Blount et al. (2006, 2007), since Tellez et al. (2005) measured perchlorate exposure in the individuals on which the effects of concern were monitored.

Recommendation: EPA needs to reconsideration its existing RfD on the basis of the Tellez et al. (2005) epidemiology study in pregnant women and their babies. This reconsideration is consistent with recommendations of the NAS (2005) on page 69 of its report.

Concern: NAS (2005, pages 9 and 112) admits that it did not follow EPA's traditional RfD method when it developed their value. Since EPA adopted the NAS RfD, the inescapable conclusion is that EPA did not follow it own RfD method either. More importantly, lack of adherence to EPA's methods will encourage others to do so as well, resulting in a potpourri of values with little resemblance to those that already exist on EPA's Integrated Risk Information System (IRIS) or elsewhere.

Recommendation: Recalculate the existing perchlorate RfD using EPA's published methods.

See the attached file for details. Reviewed using developmental reserve. [See PDF Docket ID EPA-HQ-OW-2009-0297-0637; Note that this attachment is identical to Docket ID EPA-HQ-OW-2008-0692-1562; responses to this comment are provided through Docket ID EPA-HQ-OW-2008-0692-1562.]

Response: See response to comment ID 28863 under comment code 2110.

EPA will consider the best available peer reviewed data in developing an NPDWR for perchlorate, including the data from the Tellez study.

Water Docket Environmental Protection Agency Mailcode: 2822T 1200 Pennsylvania Avenue, NW Washington, DC 20460

Re: Docket ID No. EPA-HQ-OW-2009-0297

Dear Sir or Madam:

At the request of the Perchlorate Study Group, I am writing as a physician and toxicologist in response to your request for comments (Fed Reg 74:41883, 08/19/09) regarding EPA's perchlorate regulatory determination. By way of introduction, I am Clinical Professor of Epidemiology and Medicine at Yale School of Medicine, Director of the Yale University Interdisciplinary Risk Assessment Forum, and a faculty member of the Yale Occupational and Environmental Medicine Program. I serve as Co-Chair of the Council on Scientific Affairs of the American College of Occupational and Environmental Medicine (ACOEM), was Editor and Course Director of the ACOEM Core Curriculum in Environmental Medicine, and served as a founding member of EPA's National Advisory Committee to Develop Acute Exposure Guideline Levels for Hazardous Substances.

1.) First and foremost, I support the Agency's decision to base its regulatory decision upon the current RfD, and not upon the findings of studies published since 2005 (Fed Reg 74:41892, 08/19/09). Over the past several years, much attention has been given to findings reported by Blount et al. (1), who analyzed data from the CDC's 2001-2002 NHANES study and performed additional analyses on NHANES urine samples.

Response: The Agency believes that the current RfD is appropriate for purposes of this regulatory determination.

EPA Comment ID: 28745
EPA Comment Code: 2110

Comment: 2. The findings of several studies conducted since 2005 suggest that the EPA- adopted reference dose of 0.7 ug/kg-day is a conservative and health-protective reference dose that has a 10-fold uncertainty factor applied to the point of departure to account for differences between healthy adults and the most sensitive population: fetuses of pregnant women who might have hypothyroidism or iodide deficiency. Consequently, additional non-standard adjustments appear unnecessary because the health of the most sensitive sub-population (fetuses and neonates) has already been considered. Application of an appropriately calculated relative source contribution (RSC) term, as was conducted during development of the December 2008 Health Advisory (HA), appears adequate and appropriate.

Response: EPA believes that the RfD indicated by the NAS is appropriate. EPA has not yet determined how best to develop the MCLG for perchlorate. EPA plans to seek comments on its development of its proposed regulation, including the MCLG, as required by the SDWA.

Commenter Name: Carol Rowan West
Commenter Organization: Massachusetts Department of Environmental Protection (MassDEP)
EPA Document ID: EPA-HQ-OW-2009-0297-0495
EPA Comment ID: 28863
EPA Comment Code: 2110

Comment: 5) Although the HRL of 2 ppb recommended above is numerically similar to the maximum contaminant level adopted by MassDEP and protective of the sensitive segment of the population, the RfDs used by the two agencies as the bases to derive the drinking water levels are different. MassDEP concluded that the National Research Council's (NRC) RfD is not protective of public health (Zewdie et al. 2009). Although uncertain, the EPA's modified PBPK analysis presented in Table 1 for a 7-day-old healthy infant supports this position. In this analysis, the infant gets about 3 times the maternal dose through breast milk at the dose equal to the point-of-departure (POD) in the NRC RfD derivation. This translates to a 7-day infant receiving about 20 ug/kg/day (0.02 mg/kg/d) dose of perchlorate through breast milk from a mother ingesting 7 ug/kg/day. This dose level is equivalent to the exposure level that resulted in significant inhibition (17 %) of iodide uptake in healthy adults in the Greer et al. (2002) study, suggesting that the factor of 10 applied to the POD by the NRC to protect sensitive individuals is insufficient. An additional uncertainty factor is required to extrapolate from LOAEL to NOAEL as 0.02 mg/kg/day is an effect level. Efforts to determine populations at risk based on the NRC RfD will yield significant underestimates of those at risk. MassDEP can support EPA's decision to not re-evaluate the NRC RfD at this time, if EPA adopts an HRL of 2 ppb or lower.

Response: With regards to conclusions of the NRC panel on the effects of perchlorate exposure, EPA believes the NRC appropriately based the RfD on iodide uptake inhibition to the thyroid, for the reasons discussed in its report. The NRC (2005) identified "the fetus of pregnant women who might have hypothyroidism or iodide deficiency" as "the most sensitive population," but also identified infants and developing children as additional "sensitive populations." Infants and young children have greater exposure to contaminants in food and water because of greater consumption of food and water on a per unit body weight basis. Therefore, these life stages may be the most vulnerable populations when their relative exposure is considered. EPA believes that infants may be

most exposed and have a greater potential for exceeding the RfD because of body weight and consumption. It is important to consider that the source of the perchlorate in breast milk is probably due to a much greater extent to the greater prevalence of perchlorate in food, than due to comparatively lesser prevalence of perchlorate in drinking water. The NRC recommended that EPA apply an uncertainty factor of 10 to the NOEL of 7.0 ug/kg for the perchlorate-induced inhibition of thyroid iodide uptake, to account for differences in sensitivity between healthy adults and the most sensitive sub-population, consisting of fetuses of pregnant women who might have hypothyroidism or iodide deficiency. Iodide uptake inhibition has been identified in the literature as an area of concern in connection with increasing the risk of neurodevelopmental impairment in fetuses of high-risk mothers. The NRC viewed the recommended uncertainty factor of 10 as conservative and protective of health, given that the NOEL is based on a non-adverse effect (iodide uptake inhibition) which precedes the adverse effect in a continuum of possible adverse biological effects of perchlorate exposure. NRC recommended that using a non-adverse effect that is upstream of the adverse effect represents a more conservative, health-protective approach to the risk assessment for perchlorate, noting that the purpose of the 10-fold uncertainty factor is to protect sensitive subpopulations in the face of uncertainty regarding their relative sensitivity to perchlorate exposure. EPA has adopted the NRC's recommendations in its "Integrated Risk Information System" (IRIS) (USEPA 2005), resulting in an RfD of 0.7 ug/kg/day, which was derived by applying a 10-fold (10x) uncertainty factor to the NOEL of 7.0 ug/kg/day. EPA used the best available peer-reviewed science, and the Agency has determined to regulate perchlorate in drinking water. EPA will be reevaluating this issue as part of the perchlorate rulemaking. Greer MA, Goodman G, Pleus RC, Greer SE. Health effects assessment for environmental perchlorate contamination: the dose response for inhibition of thyroidal radioiodine uptake in humans. Comment: III. OTHER COMMENTS

In Section IV of the Notice, EPA discusses its consideration of studies published since EPA adopted the NRC RfD for perchlorate. The Notice states:

EPA's preliminary regulatory determination is based on NRC's (NRC, 2005) recommendation to use data from the Greer et al. (2002) study as the basis for the perchlorate RfD/risk assessment. Since the publication of the NRC report, researchers have investigated perchlorate occurrence in humans by analyzing for perchlorate in urine and breast milk-such biomonitoring data has the potential to better inform EPA's analysis of exposure to perchlorate through food and water and to provide insight into the possible interactions of other physiologic conditions (e.g., iodine deficiency) with perchlorate ingestion. EPA's preliminary regulatory determination described the consideration of

these studies, many of which were published after the NRC report (including, but not limited to, Blount et al. (2006 and 2007), Steinmaus et al. (2007), and Amitai et al. (2007)).

EPA's conclusion to this section is:

EPA agrees that additional important data have become available since the RfD was derived in 2005. However, EPA has evaluated the new data and has decided to make the regulatory determination based upon the current RfD.

The weight-of-scientific evidence supports this EPA conclusion.

Response: EPA believes that the RfD indicated by the NRC is appropriate. As discussed in this FR notice, EPA has decided the model does not directly bear on the current decision regarding the need for a NPDWR for perchlorate. EPA is continuing to evaluate whether the model could be used in setting a NPDWR for perchlorate.

Commenter Name: Anila Jacob
Commenter Organization: Environmental Working Group (EWG)
EPA Document ID: EPA-HQ-OW-2009-0297-0499
EPA Comment ID: 28927
EPA Comment Code: 2110

Comment: - EPA must modify the RfD that is the basis for its standard setting to include a substantial body of peer-reviewed science published since 2002, including two large, high quality epidemiologic studies from the CDC (Blount et al 2006a, Blount et al 2006b). In addition to these new studies, peer reviewed analyses of the study that forms the basis for the current RfD (Greer 2002) have revealed fatal flaws with this work. A study with such fundamental and well-documented shortcomings cannot be used as the basis to determine national safety standards for exposure to this potent thyroid toxin.

Response: See response to comment ID 28863 under comment code 2110.

Commenter Name:
Commenter Organization: Intertox, Inc.
EPA Document ID: EPA-HQ-OW-2009-0297-0662
EPA Comment ID: 29077
EPA Comment Code: 2110

Comment: EPA is justified in making a regulatory determination based upon the current Reference Dose (RfD), which includes a 10-fold uncertainty factor (UF) to account for sensitive life stages; further reductions for sensitive life stages are duplicative and not scientifically justified. Importantly, authoritative bodies concur that the RfD is based on a No Observed Effect Level (NOEL), which is a more conservative approach than EPA's traditional use of a No Observed Adverse Effect Level (NOAEL). In establishing the threshold for IUI-which is defined by the National Academy of Sciences as a nonadverse effect-as the point of departure, EPA has already ensured that downstream adverse effects due to perchlorate (which to date have not been reported in humans exposed to perchlorate at environmental levels) will not occur (NRC, 2005). Since much information regarding

the perchlorate mechanism of action is known, EPA should use PBPK modeling based on the best science rather than the estimations in the alternative HRL calculations.

Response: EPA believes that the RfD indicated by the NRC is appropriate. As discussed in this FR notice, EPA has decided the model does not directly bear on the current decision regarding the need for a NPDWR for perchlorate. EPA is continuing to evaluate whether the model could be used in setting a NPDWR for perchlorate.

EPA Comment Code: 2150 EPA's decision not to seek further input from the NRC on issues related to perchlorate

Response to Comment Code 2150: On October 10, 2008, EPA published a Federal Register notice presenting the Agency's preliminary regulatory determination for perchlorate and supporting rational for this determination, in accordance with the Safe Drinking Water Act (SDWA) (Federal Register Vol. 73, No. 198, p. 60262). In this October 10, 2008 Federal Register notice, EPA determined that a national primary drinking water regulation (NPDWR) for perchlorate would not present a meaningful opportunity for health risk reduction for persons served by public water systems. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, the opportunity for health risk reduction through a national primary drinking water standard, and also requested comment on whether further review by the NRC would be warranted. In January of 2009, EPA announced that the Agency planned to seek additional input from the National Research Council (NRC) on perchlorate. The NRC previously studied perchlorate health implications from March, 2003 until they issued their report in January, 2005 (NRC 2005). EPA has compiled and evaluated additional scientific studies relevant to perchlorate health effects and exposure available in the scientific literature since publication of the 2005 NRC report. EPA also has obtained peer review and public comment on the Agency's analysis of a number of these studies. The Agency currently believes that further review by the NRC would unnecessarily delay regulatory decision making for perchlorate. EPA also notes in this August 19, 2009 Federal Register notice that if the Agency were to make a final determination to regulate perchlorate, the Agency, in accordance with the SDWA, would seek review by the Science Advisory Board prior to proposal of any maximum contaminant level goal and national primary drinking water rule. Therefore, EPA is not, at present, planning to request additional NRC review of issues related to perchlorate.

EPA Comment Code: 2150

Comment: EPA's Commitment to Use Sound Science

In January of this year, EPA announced that it would reevaluate the science regarding perchlorate's potential health effects, with particular emphasis on evaluating the effects of perchlorate exposure on infants and young children. The Agency further announced that it planned to seek additional advice from the National Research Council ("NRC") on perchlorate before making a final determination. Since the time NRC last issued its January 2005 report on perchlorate,[FN1: National Research Council, Health Implications of Perchlorate Ingestion, National Academies Press, Board on Environmental Studies and Toxicology (January 2005). Subsequently in 2005, EPA adopted the

NRC recommended reference dose of 0.0007 mg/kg per day, which translates to a drinking water equivalent level of 24.5 ppb ("DWEL"). In January 2006 EPA's Superfund office issued guidance adopting the NRC reference dose and DWEL of 24.5 ppb as the recommended value to be considered as the preliminary remediation goal to guide perchlorate assessment and cleanup at Superfund sites. In January 2007, EPA reported that it had collected sufficient occurrence data, and that further monitoring was not needed for the Agency to make a regulatory determination. 72 Fed. Reg. 367 (January 4, 2007). In October of 2008, EPA announced a preliminary determination not to regulate perchlorate, noting that less than 1% of water systems have perchlorate levels above the health reference level. EPA concluded that perchlorate failed to meet two regulatory criteria (i.e., that a contaminant occur frequently at levels of health concern, and that establishing a national drinking water standard would provide a "meaningful opportunity for health risk reduction"). Then, in January 2009, EPA announced that it was replacing the perchlorate preliminary remediation goal of 24.5 ppb with an interim health advisory, establishing a nonenforceable concentration of contaminants in drinking water at which no adverse health effects are expected to occur, of 15 ppb. In the face of this uncertainty and regulatory history, debate over the science of perchlorate health risks has continued.] EPA has compiled and evaluated additional scientific studies relevant to perchlorate health effects and exposure that were not available to the NRC. However, in its August 19, 2009 Notice, EPA announced that it would, in fact, not seek further review by the NRC because it believed such review would "unnecessarily delay" regulatory decision making for perchlorate.

Concerns about protection of human health and the environment must always be in the fore front of our thinking, but to do so properly, sound science should not be sacrificed in the interest of mere expediency. The APA firmly believes that EPA should ask the NRC to review the new information to assist EPA with its determination. EPA has spent years assessing perchlorate's health effects and occurrence to determine whether a national standard is warranted.[FN2: Under the Safe Drinking Water Act ("SDWA"), [Sec] 1412, to regulate a contaminant in drinking water, EPA must determine that it meets three criteria: (1) The contaminant may have an adverse effect on human health, (2) the contaminant is known to occur or there is a substantial likelihood that the contaminant will occur in public water systems with a frequency and at levels of public health concern, and (3) regulation of such contaminant presents a meaningful opportunity for health risk reduction for persons served by public water systems. These legal criteria are premised on the use and application of sound science.] In the interest of obtaining the best available scientific information and advice, a comprehensive NRC review should be preferred.[FN3: The Notice specifically requested comment upon whether further review by the NRC is warranted, 74 Fed. Reg. 41884, and noted that if the Agency were to make a final decision to regulate perchlorate, it would seek review by the Science Advisory Board ("SAB") prior to proposal of any maximum contaminant level goal and national primary drinking water rule. Id. However, the statutorily required review by the SAB under section 1412 of the SDWA to comment prior to setting the levels of a maximum contaminant level goal and national primary drinking water regulation, should not be a substitute for the timely scientific review of the NRC prior to the Agency's predicate decision making responsibility under the SDWA on whether regulation is warranted in the first place. Rigorous application of scientific review and sound science principles, especially by outside independent entities, should inform each statutorily- required regulatory step and decision, not only the final one. Indeed, it is the first step that has been the most controversial and it is that process of reevaluation in which the Agency is currently engaged.]

EPA has, itself, recognized the significant scientific complexity involved here. "The public comments EPA received pursuant to the October 10, 2008, notice of preliminary regulatory determination and from the peer review of the supporting documents underscore the complexity of

the scientific issues regarding the regulatory determination for perchlorate in drinking water." 74 Fed. Reg. 41884. Given that complexity, thorough review, analysis, and input from all available sources, including the NRC, should be sought to ensure full Agency consideration of the latest and best available science and thinking.

EPA's website addressing "Using Sound Science" reiterates the importance of thorough scientific review:

We depend upon sound science to do our work. Scientific information is especially important in the development of regulations. Whether we are developing a standard to protect the public from a newly recognized risk or defining monitoring requirements to gauge how well an environmental control is working, we incorporate the most current and credible scientific information into our regulation development process. . . . EPA relies, to the extent possible, on information that has undergone thorough peer review. During peer review, qualified, independent experts provide critical assessments to ensure that activities are technically supportable, competently performed, properly documented, and consistent with established quality criteria.... We also regularly solicit outside expertise from the National Research Council, other federal agencies with related responsibilities, and other scientific organizations.[FN4: Using Sound Science, available at: http://www.epa.gov/lawsregs/brochure/science.html]

This Administration has reaffirmed the federal government's commitment to the principles of scientific integrity and the incorporation of full and open scientific review in all its policy-making functions. On March 9, 2009, the President issued his Memorandum on Scientific Integrity, directed to the heads of executive departments.[FN5: Available at: http://www.whitehouse.gov/the_press_office/Memorandum-for-the-Heads-of- Executive-Departments-and-Agencies-3-9-09/), published at 74 Fed. Reg. 10671 (March 11, 2009).] The President stated:

"science and the scientific process must inform and guide decisions of my Administration on a wide range of issues, including improvement of public health [and] protection of the environment."

He charged the Director of the Office of Science and Technology Policy with "the responsibility for ensuring the highest level of integrity in all aspects of the executive branch's involvement with scientific and technological processes." As the President further emphasized:

The public must be able to trust the science and scientific process informing public policy decisions. Political officials should not suppress or alter scientific or technological findings and conclusions. If scientific and technological information is developed and used by the Federal Government, it should ordinarily be made available to the public. To the extent permitted by law, there should be transparency in the preparation, identification, and use of scientific and technological information in policymaking.

In response to the March 9 Presidential Memorandum on Scientific Integrity, we understand that EPA's Office the Science Advisor ("OSA") has been working with the White House Office of Science and Technology Policy ("OSTP") to develop recommendations for the President and with EPA's Science Policy Council to establish the EPA position on the topic. See http://www.epa.gov/osa/scientific_integrity.htm. As the OSA has explained:

The role and use of science at EPA are determined by the nature of scientific information and how it fits within the context of Agency decision-making. Scientific information--whether it comes from EPA, other agencies, academia, the regulated community, or other sources-- always includes some degree of uncertainty and is subject to varying interpretations. For example, assessments of risks to humans from exposure to chemicals are often based on tests in which laboratory animals are given high doses of a chemical. Effects seen in the animals may or may not appear in humans, who are typically exposed to much lower doses and whose bodies may metabolize the chemicals differently. In addition, there are often different scientifically justifiable ways to conduct risk assessments, and the method chosen by the assessor can significantly impact the risk estimate.

Scientific knowledge is not only uncertain, but also dynamic. Through research that is designed to reduce uncertainties, our understanding increases and, as a result, we change our assumptions about the impacts of environmental problems and how they should be addressed....

Science does not drive EPA's policy and regulatory decisions, but rather, along with other relevant factors, informs and supports those decisions. Implementation costs and technological feasibility, local autonomy versus federal control, and justice and equity--all of which impact our quality of life and standard of living--are among the considerations that need to be factored into EPA's decisions without compromising scientific integrity, the Agency's mission, or statutory mandates. The impacts or limitations of these non-science factors, as well as the current state-of-the-science, will influence how scientific considerations are brought to bear on a particular environmental problem facing the Agency.[FN6: See http://www.epa.gov/osa/osa.htm.]

Administrator Jackson recently testified in front of the U.S. Senate Committee on Environment and Public Works on "Scientific Integrity and Transparency Reforms at the Environmental Protection Agency" on June 9, 2009,[FN7: Available at: http://www.epa.gov/ocir/hearings/.] that "[t]he public health and environmental laws that Congress has enacted depend on rigorous adherence to the best available science... While the laws that EPA implements leave room for policy judgments, the scientific findings on which of these judgments are based should be arrived at independently using well-established scientific methods, including peer review, to assure rigor, accuracy, and impartiality." In her testimony, Administrator Jackson acknowledged that, "Environmental science is complex and multi-faceted, and able scientists may not always agree on what methodologies should be employed or how studies should be interpreted. I am committed to fostering a culture of robust scientific debate and discussion within the Agency, recognizing that in the end senior scientists must take responsibility for resolving differences of opinions using established science policies and their best professional judgment."

APA respects and supports the Agency's paramount obligation to protect water quality and public health. We respectfully ask that the Agency take its own commitment to use sound science, as well as the directive of the White House to observe the highest principles of scientific-integrity, into account as it decides whether to ask the NRC or others to perform additional scientific review on the admittedly complex questions surrounding perchlorate. EPA has sought these additional comments from the public in "an effort to ensure consideration of all the potential options for evaluating whether there is a meaningful opportunity for human health risk reduction of perchlorate through a national primary drinking water rule." 74 Fed. Reg. 41883. No less so should EPA again seek the widely respected expertise, comments and advice of the NRC on this most difficult of public health issues, especially where that NRC review has proved so beneficial in the very recent

past to a full and robust consideration of the scientific data and uncertainties that must inform sound public health policy.

Because the science and policy judgments underlying your decision-making for regulating perchlorate in drinking water are extraordinarily complex and will impact not only public health but also the environment and our businesses, full consideration of all available scientific information as well as all available peer review of that information, is clearly warranted. Please reconsider your decision not to seek further review by the NRC of all the critical studies, data, and risk analyses in this important process, so that EPA may have the benefit of the most rigorous and complete analysis of the available scientific data on which to deliberate and act. To ensure that this commitment to scientific integrity be met, while EPA could simply look at the same information again and ask the public if it has any new thoughts on how to interpret that information, we would respectfully suggest EPA request, as it originally intended to do,[FN8: See Congressional Research Service, CRS Report to Congress, Perchlorate Contamination of Drinking Water: Regulatory Issues and Legislative Actions, August t, 2009, p. 5.] that the NRC study and provide to EPA an evaluation of impacts to infants and young children from perchlorate and evaluate the more recent studies, EPA's use of models, and its derivation of the 15 ppb health reference level, as well.

Thank you for your consideration of our comments and our request that the Agency take advantage of the full panoply of available means to incorporate rigorous scientific review into your process for reevaluating the risks, and the EPA's proposed additional approaches to analyzing the data, related to EPA's perchlorate determination. EPA should receive benefit of further NRC analysis of the latest data which will ensure that the Administration's commitment and mandate to use of sound science in policy- making is fulfilled.

Respectfully submitted, Julie L. Heckman Executive Director cc: Administrator Lisa Jackson Assistant Administrator for Water

Response: EPA is committed to the application of sound science and the principles of scientific integrity in its decision-making. The proposed path forward is designed to ensure adherence to both. See response to comment ID 28835 under comment code 2150.

Comment: Finally, we wish to discourage EPA from again referring the perchlorate assessment to the National Research Council (of the National Academies of Sciences) for further review. The last time (2005) the NRC reviewed perchlorate, it overstepped its charge and recommended a reference dose. This usurped EPA's authority and made it difficult for the public to comment at a key phase in the regulatory process. Furthermore, NRC committees meet a handful of times over many months. A referral would delay the process without a great deal of additional review.

Response: See response to comment code 2150 and comment ID 28822 under comment code 2150.

Comment: HISTORY OF DELAY

EPA had evidence in the 1980's that perchlorate was leaching from military dumpsites into groundwater, as documented in a 1985 interagency letter from EPA to the Centers for Disease

Control and Prevention (CDC) reporting on levels as high as 300-800 ppb "potentially affecting 32,000 to 42,000 households."[FN24: As documented in: Sass J. U.S. Department of Defense and White House working together to avoid cleanup and liability for perchlorate pollution. Int J Occup Environ Health. 2004. Jul-Sep;10(3):330-4.] EPA set a provisional RfD of 0.0001 mg/kg/day in 1992; this would have been equivalent to an MCL of 3.5 ppb in water, presuming an adult average body weight and daily water consumption, and presuming no other sources of perchlorate.[FN25: As documented in: Sass J. U.S. Department of Defense and White House working together to avoid cleanup and liability for perchlorate pollution. Int J Occup Environ Health. 2004. Jul- Sep;10(3):330-4.] It has been 17 years since that provisional RfD, and in that time the science supporting that RfD has grown significantly stronger, along with public concern and Agency interest. Moreover, the RfD now finalized is 0.7 ug/kg/day, not dramatically different from the provisional RfD 17 years ago, given the extremely lengthy delay.

EPA's progress on this assessment has been extensively and repeatedly reviewed by the interagency panel that was created in 1998 as a partnership between EPA, the U.S. Department of Defense , and other federal agencies to review perchlorate issues.

In 2002, EPA issued an External Review Draft that recommended a limit of 1 ppb in drinking water. This was sent to the NRC for review in 2004, which resulted in the recommended oral RfD of 0.0007 mg/kg/day, adopted by EPA in 2005.

REQUEST FOR COMMENT ON NRC REVIEW

NRDC Response: Further Review by NRC Not Warranted

After over 17 years of accumulated science (documented above), two EPA toxicological reviews (1998, 2002), and a lengthy NRC review (2004), it is past time for EPA to take effective regulatory action to protect people's health by preventing exposure to perchlorate. Therefore, NRDC supports the Agency's belief that further review by the NRC would create an unnecessary delay without adding anything to the scientific rigor of the Agency's determination.

NRDC would likely support the Agency if it requested a review by its Scientific Advisory Board, since it would be more rapid and less costly than an NAS review, while providing scientific oversight.

Response: See the response to comment ID 28822 under comment code 2150.

EPA Comment Code: 2150

Comment: Given these significant concerns, EPA should also move forward with its alternative proposal to seek additional input from the National Research Council of the NAS, regarding the health impacts of (synthetic and natural) perchlorate, and should specifically request input regarding the issues presented in these comments, including the problems associated with the Greer NOEL and the RfD.

Response: The NRC previously studied perchlorate health implications from March, 2003 until they issued their report in January, 2005 (NRC, 2005). EPA has compiled and evaluated additional scientific studies relevant to perchlorate health effects and exposure available in the scientific literature since publication of the 2005 NRC report. EPA also has obtained peer review and public comment on the Agency's analysis of a number of these studies. The Agency currently believes that further review by the NRC would unnecessarily delay regulatory decision making for perchlorate. EPA also notes in this August 19, 2009 Federal Register notice that if the Agency were to make a final determination to regulate perchlorate, the Agency, in accordance with the SDWA, would seek review by the Science Advisory Board prior to proposal of any maximum contaminant level goal and national primary drinking water rule. Therefore, EPA is not, at present, planning to request additional NRC review of issues related to perchlorate.

EPA Comment Code: 2150

Comment: Review By NAS. In the October 10, 2008 Federal Register notice (73 FR 60262) EPA stated that it would send its review of the science surrounding perchlorate again to the NAS. AMWA still believes the analysis should go to NAS for review although the association's reasons have shifted in light of the agency's new analysis of alternative HRLs. Specifically, AMWA believes a review by NAS of EPA's new analysis and methodology explained in this NODA for determining alternative HRLs is judicious because this analysis is the first time the agency has applied its 2005 Guidance. It is also prudent as EPA is asking for comment on using the PBPK model for evaluating the relative sensitivity of the various life stages to perchlorate exposure in drinking water.

AMWA recommends that EPA send both the revised PBPK model as well as the analysis used to derive alternative HRLs to NAS for review because the potential precedent that will be set if these analyses are used in rulemaking have significant ramifications for how policy is developed. Particularly where endocrine disrupting compounds are concerned, the impacts of particular chemicals on children's development must be properly characterized and modeled. Specifically, AMWA recommends that an NAS review panel be formed to address the questions posed in section A.4 of 74 FR 41886. In addition, NAS should be asked to determine the merits of the alternative approaches for calculating HRLs detailed in section B.3 (74 FR 41887-41889) and specifically with regard to EPA's request for comments in B.4 (74 FR 41889).

AMWA has additional comments related to the NAS review later in this comment letter where EPA's specific requests for comment are identified.

Response: See the response to comment ID 28822 under comment code 2150.

EPA Comment Code: 2150

Comment: Part II: Specific EPA requests for comment

74 FR 41884: "EPA requests comment upon whether further review by [the National Research Council] NRC is warranted. EPA also notes that if the Agency were to make a final determination to regulate perchlorate the agency would seek review by the SAB prior to proposal of any MCLG or national primary drinking water rule."

Response: In previous comments, AMWA suggested that EPA send its review of the perchlorate science to NAS for review by 2011 (or sooner if the agency so desires). As expressed earlier in this comment letter, AMWA still believes the analysis should go to NAS for review although the association's reasons have shifted in light of the agency's new analysis of alternative HRLs.

AMWA disagrees with EPA that another review by NAS/NRC could slow the process. Previous NAS/NRC panels have finished their work in short time spans and EPA could convene a panel concurrent with the development of a perchlorate regulation, should the agency make a determination to regulate perchlorate.

EPA states in the NODA that it will have the Science Advisory Board (SAB) review any regulatory determination made prior to proposal of the regulation. This is required in Section 1412 of the SDWA and AMWA agrees that this is a good and appropriate course of action. However, a SAB review would likely focus on the entire perchlorate regulatory proposal rather than specific components of the proposal.

As a result, AMWA believes that a focused NAS/NRC review of the alternative HRL analysis that used EPA's 2005 Guidance as well as the 2008 Child-Specific Exposure Factors Handbook is necessary because of the broad potential policy implications for OGWDW and the analysis of future regulations. In addition, the mission of the NAS, in particular NRC, "is to improve government decision-making and public policy, increase public education and understanding, and promote the acquisition and dissemination of knowledge in matters involving science, engineering, technology, and health. The institution takes this charge seriously and works to inform policies and actions that have the power to improve the lives of people in the U.S. and around the world." (http://sites.nationalacademies.org/NRC/index.htm)

A NAS/NRC panel should be selected with expertise in mind to address the questions put forward in the FR notice. The new analysis to determine HRLs, as well as the agency's additional consideration for using the PBPK model, should also be peer reviewed by experts who are well versed in modeling.

Response: See the response to comment ID 28822 under comment code 2150. The SAB will consider all aspects of the NPDWR, including the scientific evaluations underlying it.

Commenter Name: Diane VanDe Hei
Commenter Organization: Association of Metropolitan Water Agencies (AMWA)

EPA Document ID: EPA-HQ-OW-2009-0297-0494
EPA Comment ID: 28835
EPA Comment Code: 2150

Comment: Should EPA decide not to seek review by NAS, AMWA strongly recommends that EPA include in the charge to SAB the requests for comment surrounding the alternative HRLs analysis found in this NODA (Section A. 4 of 74 FR 41886). In addition, NAS should be asked to determine the merits of the alternative approaches for calculating HRLs detailed in section B. 3 (74 FR 41887-41889) and specifically with regard to EPA's request for comments in B.4 (74 FR 41889). AMWA also strongly recommends that EPA provide at least six months for SAB to review the alternative HRL analysis and PBPK model as it relates to this analysis. EPA should also take care to ensure that there are sufficient reviewers with the proper expertise for the task.

Response: See response to comment ID 28822 under comment code 2150. EPA will ensure that the charge to the SAB and the composition of the panel are appropriate for the review of the entire scientific underpinnings of the NPDWR.

Comment: Section II: Background

MassDEP supports EPA's opinion that further review by the National Research Council (NRC) will delay regulatory decision-making and supports EPA's current plan to publish alternative approaches to interpreting the data on perchlorate and to consider public comments towards making a regulatory decision on perchlorate in drinking water.

Response: EPA agrees with the commenter as discussed in the response to comment ID 28822 under comment code 2150. Also, see response to comment code 2150.

EPA Comment Code: 2200 Use of NHANES biomonitoring data for health effects evaluation

Response to Comment Code 2200: After a report prepared by the NRC (National Research Council) on "Health Implications of Perchlorate Ingestion" (NRC 2005) was released, several papers were published that investigated whether biomonitoring data associated with the National Health and Nutrition Examination Survey (NHANES) could be used to discern if there was a relationship between perchlorate levels in the body and thyroid function. Blount et al., (2007) published a study examining the relationship between urinary levels of perchlorate and blood serum levels of TSH and total T4 in 2,299 men and women (ages 12 years and older) who participated in CDC's 2001–2002 NHANES. Blount et al. (2007) evaluated perchlorate along with a number of covariates known or likely to be associated with T4 or TSH levels to assess the relationship between perchlorate and these hormones, and the influence of other factors on this relationship, including gender, age, race/ethnicity, body mass index, serum albumin, serum cotinine (a marker of nicotine exposure), estimated total caloric intake, pregnancy status, post-menopausal status, premenarche status, serum C-reactive protein, hours fasting before sample collection, urinary thiocyanate, urinary nitrate, and use of selected medications. The Blount et al. (2007) study found that perchlorate exposure was a statistically significant predictor of thyroid hormones (T4) in women with urinary iodine levels <100 ug/l, but not in men. Blount et al. (2007) noted several limitations of their study and recommended that their findings be affirmed in at least one more large study focusing on women with low urine iodide levels. Since their study was cross-sectional in design, it also cannot be concluded whether or not the association between perchlorate and thyroid hormone levels is causal, or is mediated by some other correlate of both, although the relationship between urine perchlorate and total TSH and T4 levels persisted after statistical adjustments for some additional covariates known to predict thyroid hormone levels (e.g., total kilocalorie intake, estrogen use, and serum C-reactive protein levels). An additional paper by Blount et al., (2006), found that almost all participants in the NHANES survey, including the participants in this first group, had urinary levels of perchlorate corresponding to estimated dose levels that are below the RfD of 0.7 μg/kg/day.

The Blount et al. (2006) study suggested that perchlorate could be a surrogate for another unrecognized determinant of thyroid function, since there are other chemicals, including nitrate and thiocyanate, which can affect thyroid function. Steinmaus et al., (2007) further analyzed the data from NHANES 2001–2002 to assess the impact of smoking, cotinine and thiocyanate on the relationship between urinary perchlorate and blood serum T4 and TSH. Thiocyanate affects the thyroid by the same mechanism as perchlorate (competitive inhibition of iodide uptake). Steinmaus et al. (2007) analyzed the NHANES data to determine whether smoking status (smoker or nonsmoker), serum thiocyanate, or serum cotinine were better predictors of T4 and TSH changes than perchlorate, or if the effects reflected the combined effects of perchlorate and thiocyanate. These authors found no association between either perchlorate or T4, and smoking, cotinine, or thiocyanate in men or in women with urinary iodine levels >100 μg/l. In addition, Steinmaus et al. (2007) found no association between cotinine and T4 or TSH in women with iodine levels <100 μg/l. However, in women with urinary iodine levels <100 μg/l, they found that an association between urinary perchlorate and decreased serum T4 was stronger in smokers than in non-smokers, and stronger in those with high urinary thiocyanate levels than in those with low urinary thiocyanate levels. The authors concluded that for these low-iodine women, the results suggest that at commonly occurring perchlorate exposure levels, thiocyanate in tobacco smoke and perchlorate

interact in affecting thyroid function, and that agents other than tobacco smoke might cause similar interactions (Steimaus et al., 2007).

EPA Document ID: EPA-HQ-OW-2008-0692-1427
EPA Comment ID: 20629
EPA Comment Code: 2200

Comment: The analyses that form the basis of docket ID No. EPA-HQ-OW-2008-0692, entitled "Drinking Water: Preliminary Regulatory Determination on Perchlorate" err significantly in the omission of critically relevant data sources. At a minimum, a critical evaluation of Blount et al (2006a) should be incorporated into the docket and the conclusions drawn therein should be revised accordingly.

Another key data source that was omitted from consideration by the EPA is the relationship between perchlorate exposure and thyroid function identified by Blount et al. (Blount et al., 2006a). Blount et al., (2006a) results are consistent with a causal relationship between perchlorate exposure and thyroid function as follows:

a. The strength of the relationship between urinary perchlorate and serum total T4 and serum TSH was greater in women with low urinary iodide (>100 ug/L).

b. The strength of the relationship between urinary perchlorate and serum total T4 and serum TSH was greater in women who smoked (Steinmaus et al., 2007).

c. Significant relationships with other ions known to affect iodide uptake were not observed.

d. Given the known variability in urinary perchlorate levels (Blount et al., 2006b) and in T4 and TSH levels (Andersen et al., 2002; Andersen et al., 2003), a very large sample size would be required to identify these relationships.

EPA cites the NAS report of 2005 (NRC, 2005) as indicating that epidemiological studies cannot identify a causal relationship between perchlorate exposure and thyroid function. However, the CDC study of 2006 represents a verification that known and predicted relationships between perchlorate exposure and thyroid function are occurring at environmental levels of perchlorate exposure in the human population. EPA must consider the statistical power of the CDC study to identify relationships of interest. These findings, furthermore, indicate that the high-dose, shortterm studies of Greer and others do not provide relevant information about the life-time low-dose exposure to perchlorate. Therefore, in the absence of a rational alternative to epidemiological studies to identify such relationships of interest in humans, EPA must employ the best available science - that of the Blount study.

EPA Comment ID: 20772
EPA Comment Code: 2200

Comment: The EPA is choosing to ignore and dismiss several scientific studies, including thise from the CDC, that show that Perchlorate can cause serious thyroid disruption in women, children, developing fetuses and newborns. This is especially concerning in the unborn and newborn, as thyroid disruption effects brain development, that can lead to mental deficiences.

Response: EPA has found that perchlorate may have an adverse effect on human health. EPA intends to develop a proposed NPDWR for perchlorate and will consider the best available, peer reviewed data as when we develop the proposed NPDWR.

Commenter Name: Lenny Siegel
Commenter Organization: Center for Public Environmental Oversight
EPA Document ID: EPA-HQ-OW-2008-0692-2019
EPA Comment ID: 20854
EPA Comment Code: 2200

Comment: More important, though it draws upon the work of the Centers for Disease Control to profile perchlorate exposures in the population, it dismisses one of its key findings: In 2006 Blount et al found that women with low iodide levels (over a third of the female population) experience decreased thyroid functions at low perchlorate exposures characteristic of much of the U.S. population. That effect could seriously impair the development of fetuses carried by such women.

But EPA states that Blount did not establish a causal relationship. That is, other factors-such as exposure to nitrates or thiocyanate, might be influencing thyroid function. It wrote, "It is also not known whether the association between perchlorate and thyroid hormone levels is causal or mediated by some other correlate of both."

That is, EPA recognizes that there is a major threat to public health, but it refuses to take action because there is a chance that the association between perchlorate and decreased thyroid function might be caused by another. unknown chemical compound. Yet EPA promises no action to track down and investigate that mysterious cause. This is unconscionable!

EPA Document ID: EPA-HQ-OW-2008-0692-1432
EPA Comment ID: 20901
EPA Comment Code: 2200

Comment: Even with the errors and bias that the use of the CIIT computer model injects into EPA's assessment, EPA still concludes that up to 2 million people may be consuming drinking water that exceeds the HRL, including tens of thousands of infants and young children. The agency then dismisses these impacts as not significant enough to justify setting a drinking water standard for perchlorate. If EPA had used CDC's real world data in it's assessment instead of the flawed computer model, a much higher number of infants, children, and women of childbearing age would be found to be at risk.

Response: See response to comment ID 28608 under comment code 2200. Also, see response to comment ID 20903 in comment code 2200 and response to comment code 5220.

After further consideration of the peer review and public comments, EPA has concluded that the PBPK modeling analysis, in the context of the perchlorate regulatory determination, is useful in examining which life stages are most susceptible to the effects of perchlorate. However, because of limitations, EPA has decided the model does not directly bear on the current decision regarding the need for a NPDWR for perchlorate.

Commenter Name: Anila Jacob
Commenter Organization: Environmental Working Group
EPA Document ID: EPA-HQ-OW-2008-0692-1432
EPA Comment ID: 20903
EPA Comment Code: 2200

Comment: Introduction:

In this assessment, EPA relies primarily on a physiologically-based pharmacokinetic (PBPK) model to estimate risks to different populations from perchlorate contamination of drinking water. This approach is somewhat suspect to begin with because it is based on a computer model, rather than on the wealth of data from human studies on perchlorate. Recent large, well-conducted human studies on perchlorate have revealed that exposure to this thyroid toxin is widespread among the U.S. population and that women with lower iodine levels are a particularly vulnerable group, in addition to breast-fed infants and young children.

Response: Several commenters supported the use of the PBPK model to inform the regulatory determination only if the significant limitations of the current model are addressed. For example, the inability of the model to reflect iodide nutritional status was cited by commenters and three of four peer reviewers as an important limitation (USEPA, 2008d). Also, several commenters stated that the risks to breast-fed infants and young children are not adequately addressed by the model. They challenged that the modeling analysis is based on average weight infants and healthy adults, while the sensitive life stages for perchlorate include premature infants and hypothyroid women.

After further consideration of the peer review and public comments, EPA concludes that the PBPK modeling analysis, in the context of the perchlorate regulatory determination, is useful in examining which life stages are most susceptible to the effects of perchlorate. For example, the model indicates that a fetus may be seven times more sensitive to the effects of perchlorate than a pregnant woman. The model also allows for the estimation of the concentration of perchlorate in breast milk (thus breast-fed infant exposure) at various maternal perchlorate exposure levels. However, because of the stated limitations, EPA has decided the model does not directly bear on the current decision

regarding the need for a NPDWR for perchlorate. EPA is continuing to evaluate whether the model could be used in setting a NPDWR for perchlorate.

Commenter Name: Anila Jacob
Commenter Organization: Environmental Working Group
EPA Document ID: EPA-HQ-OW-2008-0692-1432
EPA Comment ID: 20909
EPA Comment Code: 2200

Comment: Background

Recent research from the CDC and the Food and Drug Administration (FDA) provide strong evidence that perchlorate exposure among the U.S. population presents potential health threats that justify strong protective measures by public health agencies. The most compelling findings from recent research from government agencies and academic scientists are summarized below:

* CDC tested 2,820 U.S. residents (ages 6 an older) in a nationally representative sample and found detectable levels of perchlorate in the urine of every person tested (Blount et al. 2006a);

* Urinary perchlorate levels in children ages 6 to 11 were 1.6 times higher than levels in adults (Blount et al. 2006a);

* CDC scientists analyzed both perchlorate and thyroid hormone levels in more that 1,000 U.S. women and found that in the one third of women with lower iodine levels, perchlorate exposure far below EPA RfD of 0.7 ug/kg/day was associated with significant changes in thyroid hormone levels (Blount et al. 2006b);

* Using CDC data, an EWG analysis found that 2 million women of childbearing age may be at risk for abnormal thyroid hormone levels during pregnancy (EWG 2006);

* CDC and academic scientists have tested a combined 118 samples of U.S. breast milk in 4 different studies and have found perchlorate in every sample tested (Dasgupta et al. 2008, Kirk et al. 2005, Kirk et al. 2007, Pearce et al. 2007);

* Breast milk studies suggest that a significant number of breast fed infants may be exposed to perchlorate at levels that exceed the EPA RfD of 0.7 ug/kg/day (Dasgupta et al. 2008, Kirk et al. 2005, Kirk et al. 2007, Pearce et al. 2007);

* FDA scientists found perchlorate in three quarters of nearly 300 commonly consumed foods and beverages; young children are exposed to perchlorate doses that fall between 50 to 56% of EPA's RfD from food alone and could easily exceed EPA's RfD with additional drinking water exposures (Murray et al. 2008);

* A recent study from scientists at the University of Texas found that breast tissue concentrates perchlorate at 3 times the rate of iodine (Dasgupta et al. 2008).

This body of data from a number of respected sources including CDC, FDA, and academic scientists provides compelling evidence that establishes widespread exposure to perchlorate among the U.S. population and toxicity in a vulnerable population (women with lower iodine levels). The findings of widespread food contamination are especially concerning for young children, who eat more food and drink more water per unit of body weight when compared to adults.

EPA's decision not to regulate perchlorate in drinking water in the face of such compelling facts is irresponsible and indefensible given the strength of the evidence for stringent regulation. In fact, EPA reached its decision by using flawed models and methodology; following are some of the most glaring reasons that this assessment is inadequate.

Response: EPA agrees that perchlorate occurs at a frequency and at levels of public concern in public water systems and intends to develop an NPDWR for perchlorate.

Commenter Name: Anila Jacob
Commenter Organization: Environmental Working Group
EPA Document ID: EPA-HQ-OW-2008-0692-1432
EPA Comment ID: 20912
EPA Comment Code: 2200

Comment: EPA relies on flawed computer model while downplaying significance of human data: As noted above, EPA relies heavily on a deeply flawed computer model that predicts RAIU inhibition at various levels of perchlorate contamination of drinking water. The dependence on such a computer model would be more understandable were there not comprehensive human data on perchlorate exposure and toxicity. However, in the last two years, government agencies like CDC and FDA, as well as prominent academic scientists, have published studies establishing widespread perchlorate exposure among the U.S. population, with especially high exposures among breast-fed infants and young children, and evidence of toxicity among women with lower iodine levels.

CDC published a ground breaking study in 2006 showing that current perchlorate exposures are associated with significant effects on thyroid hormone levels in women with low urinary iodine levels. EPA deliberately downplays the significance of these findings, noting that CDC findings are contradicted by another study: "Results from studies of the effects of perchlorate exposure on hormone levels have been mixed. One recent study did not identify any effects of perchlorate on blood serum hormones (Amitai et al. 2007), while another study (Blount et al. 2006b) did identify such effects" (EPA 2008).

However, when the Amitai et al. study is reviewed, it is clear that the results of this study do not contradict the results from Blount et al.; in fact, the study authors themselves note, "Based on differences in iodine intake and life stages for the two studies, our findings do not contradict those of Blount et al." (Amitai et al. 2007). Yet, EPA maintains that the results from Amitai et al. provide evidence to doubt CDC results although the two studies are completely different and the CDC study is the only one to have established unique vulnerability to perchlorate among women with lower urinary iodine levels. By raising doubts about the validity of CDC findings, despite no scientific justification, EPA is able to downplay the significance of these findings to justify excluding them in their assessment.

Response: See response to comment ID 20909 under comment code 2200. Also see responses to comment IDs 29078 regarding the Blount et al. study and 20903 regarding PBPK modeling under comment code 2200.

Commenter Name: Caroline Baier-Anderson, PhD

EPA Comment ID: 20946
EPA Comment Code: 2200

Comment: CDC Studies Reveal Relationships between Perchlorate Exposure and Thyroid Hormones that Make Biological Sense

CDC researchers evaluated the relationship between urinary levels of perchlorate (which was found in every individual tested and at significantly higher levels in children, and serum levels of TSH and total T4 in 2,299 men and women, >=12 years of age, participating in the CDC-sponsored National Health and Nutrition Examination Survey (NHANES) during 2001-2002 (Blount et al. 2006, 2007). This study found that:

* All individuals tested were exposed to perchlorate. * Children had significantly higher levels of perchlorate exposure, * For all women >=12 years of age, multiple regression analysis found urinary perchlorate to be a significant predictor of serum TSH and a significant predictor of serum T4. * For women with urinary iodine < 100 ug/L, multiple regression analysis found perchlorate to be a significant predictor ($p < 0.0001$) of T4 with a coefficient for log perchlorate of -0.8917. * Perchlorate was also a significant predictor ($p = 0.0010$) of log TSH with a coefficient of 0.1230.

Hence, the results of the Blount study more closely reflect our understanding of the biological and toxicological processes pertaining to thyroid homeostasis, both in terms of thyroid hormone variability and the role of iodine. The researchers conclude that "[i]ncreased urinary perchlorate was associated with increased TSH and decreased T4 for women with urinary iodine levels < 100 ug/L, a group possibly more susceptible to competitive inhibition of thyroid iodine uptake by perchlorate. The statistically significant associations of urinary perchlorate with decreased serum T4 and increased serum TSH were consistent with competitive inhibition of iodide uptake."

The Blount study also validates findings of previous CDC study that 36 % of women in the National Health and Nutrition Examination Survey (NHANES), 2001-2002, had low iodine intake (< 100 ug/L urinary iodine) (Caldwell et al. 2005) , which translates to approximately 43 million US women (Pirkle 2007).

Comment: EPA Fails to Recognize the Importance of Iodine and Individual Variability

On page 60268 of the Federal Register Notice, EPA suggests that a study by Amitai et al. (2007) provides information that contradicts the findings of the Blount study, stating that measured T4 values were not associated with perchlorate levels, despite the fact that the perchlorate levels were much higher than in the CDC study. Amitai et al. directly address this comparison, asserting that because of differences in the study population between the Amitai and Blount studies, the studies are not contradictory:

"A previous study of pregnant women in the coastal areas of Israel indicates iodine sufficiency (urinary iodine median=143 ug=L, mean=130 ug=L) based on World Health Organization (WHO) criteria. Another important difference between the current work and the Blount et al.'s study is the study population: we examined thyroid function in neonates, while Blount et al. studied adults and adolescents. Based on differences in iodine intake and life stage for the two studies, our findings do not contradict those of Blount et al." (emphasis added) (Amitai et al. page 848).

Another earlier study evaluating high levels of exposure to perchlorate (the Chilean study) also involved a population that was iodine sufficient (Tellez et al. 2005). Taken together these studies indicate they iodine sufficiency is a critical component of resistance to perchlorate effects. With over 1/3 of US women demonstrating insufficient iodine intake, iodine status must be considered as an important characteristic of the exposed population.

EPA's failure to appropriately account for both individual variability and iodine status ignores important biological and toxicological considerations and has contributed to the selection of a reference dose that is not adequately protective of sensitive subpopulations.

We strongly recommend that the CDC data analyzed in the study by Blount et al. 2006 and Blount et al. 2007 be used as the basis for the derivation of a new reference dose. One option would be to estimate perchlorate dose from urinary perchlorate using an equation developed by Mage et al 2004 and applied by Blount et al. 2007. EPA could then estimate benchmark doses of perchlorate associated with benchmark responses for abnormally low T4 serum concentrations and abnormally high serum TSH concentrations in women with low urinary iodine excretion. EPA could use the BMD low (representing the lower limit of a one- sided 95% confidence interval), which more accurately reflects the statistical power inherent in the study design than the NOAEL (or NOEL, or LOEL for that matter), and more efficiently utilizes the dose-response data while being less sensitive to the spacing of doses. An uncertainty factor may be necessary to ensure the protection of the fetus and neonate. There are likely to be other approaches to data analysis that accounts for sensitive subpopulations, including individual variability, iodine status and windows of vulnerability and we encourage EPA to re-evaluate these options.

Response: See response to comment ID 29078 under comment code 2200. EPA accounts for individual variability by incorporation of an intraspecies uncertainty factor in the derivation of the RfD.

Comment: This value could be further checked against the NHANES data:

The effective perchlorate equivalent NOEL (NOEL3) as explained before is 7.04 + 5.8 = 12.8 ug/kg-day. This, as explained before, leads to a new RfD of 1.28 ug/kg-day applying the same UF of 10.

The background of the other 2 goitrogens represents 40% of NOEL3 (5.8/12.8= 0.4) (and the perchlorate background 0.3%).

Therefore the RfD for perchlorate alone for the general population would be 1.28x 0.6 = 0.77 ug/kg-day and the HRL would be 27 ppb.

This is very close to the 26.7 ppb assigned above as HRL for perchlorate alone in the perchlorate-nitrate cup if the nitrate HRL would also be subject to an UF of 10 and it is also close to the current EPA DWEL of 24.5 ppb.

In any case it would not have much sense as a public health policy and in particular in terms of thyroid protection to try to arrive at the most accurate DW HRL for perchlorate and leave the nitrate MCL at such levels that this effort would be completely nullified.

Therefore it should be recommended to set a joint HRL of 45 ppb perchlorate equivalent for nitrate and perchlorate combined.

Response: See response to comment ID 29078 under comment code 2200. EPA cannot comment on a value for combined nitrate and perchlorate because that has not been peer reviewed.

Comment: The Blount (2006) Analysis of Perchlorate Data has Several Limitations and EPA Should not Rely on its Conclusions to Make Regulatory Decisions.

The argument has been made that the Blount (2006b) results, which show a slight correlation between perchlorate in urine and changes in thyroid hormone levels in women with sub-optimal iodine levels, should be given considerable weight by EPA in making its regulatory determination for perchlorate. This work has several limitations which necessarily impede its use in drawing conclusions regarding the health effects of perchlorate, particularly for purposes of regulatory decision making. Chief among these is the fact that Blount (2006b) does not establish direct causation, only an association between two independent data sets. A number of intervening factors could cause or contribute to the reported decrease in thyroid hormone levels. Moreover, the Blount

(2006b) results conflict with the overwhelming body of scientific evidence showing no effect on the thyroid at environmentally relevant levels. Dr. Blount himself has acknowledged the limitations of his results. Similar concerns have been raised by independent organizations such as the American Thyroid Association.

The California agricultural industry appreciates US EPA's consideration of our comments on its preliminary regulatory determination for perchlorate. We remain committed to working with US EPA, FDA and individual states to preserve the safety of our products and their contribution to balanced, heallthy diets.

Sincerely,

Comment: 7. Next, your letter raises the issue of the NHANES 2001-2002 survey results and the Blount et al. 2006b study.

It is important to note that the results of the NHANES survey reveal that the US population is not exposed to levels of perchlorate that could cause an adverse effect, even when all exposure sources - in food and water - are considered. There has been considerable discussion over the role of the Blount study in the regulatory decision-making process. Those who support its use point to the specific finding that perchlorate levels were a negative predictor of total T4 and a positive predictor of TSH in women with urinary iodide less than 100 μg/L. While the findings of the study are interesting, the specific finding at issue is not able to determine causation and is simply based upon an association between two variables. The study directly conflicts with the large number of studies that have shown no effect at environmental levels. Government agencies and private organizations, including the Agency for Toxic Substances and Disease Registry, the American Thyroid Association and the Toxicology Excellence for Risk Assessment (TERA), have identified several limitations concerns with the Blount study. As a result they recommend that based on its status as solely an

associational study and as well as the numerous limitations, it should not be used in regulatory decision-making.

ATSDR (2008) reviewed the Blount et al. (2006b) study in their assessment. ATSDR did not believe that it merited any special consideration over other studies in the well developed perchlorate literature database. They stated that their decision "...was made after a careful evaluation of the NRC report and of studies that have been published after the NRC (2005) report. The results from newer studies do not change the bottom-line recommendation" (ATSDR, 2008).

The lead author, Dr. Benjamin Blount, has acknowledged several limitations with the study and that its results require validation. At an NAS workshop on risk assessment considerations for thyroid active compounds [FN5: National Research Council Fifth Workshop of the Standing Committee on Risk Analysis Issues and Reviews, Risk Assessment Considerations for Interpretation of Bioassay Data and Human Biomonitoring Data for Thyroid-Active Compounds: Issues of Variability, Critical Reproductive-Developmental Periods, and Cross-Species Comparisons, May 15-16, 2008.], Dr. Blount reviewed the results of this study and identified several limitations with the study:

* due to other missing data, perchlorate could be a surrogate for an unknown variable;

* the study is only a cross-sectional association, recognizing that it does not establish a direct causation between perchlorate levels and thyroid hormone levels;

* although this study looked at total T4, free T4 is a better measure, and

* the study was based upon a weak iodine assessment. [FN6: Ben Blount, Biomonitoring Data on Thyroid-Active Compounds: Database and Issues Regarding Variability and Interpretation, presented at NAS workshop in note 1 above, May 15, 2008.]

8. Please see the attached copy of our comments recently submitted to the EPA docket for a more extensive discussion regarding concerns and limitations of the Blount study and its inappropriate use for regulatory decision-making.

Comment: RE: Docket ID No. EPAHQ- OW-2008-0068 Comments on the US Environmental Protection Agency's Preliminary Regulatory Determination on Perchlorate November 28, 2008

I am submitting these comments unanimously since I am employed in an organisation that may not consider these comments acceptable.

Thank you for the opportunity to comment on the USEPA Office of Water's Preliminary Regulatory Determination on Perchlorate.

Comment subject

EPA refers to the Blount et al., (2006b) study and EPA mentions that in that study other covariates were evaluated besides perchlorate.

Of those covariates only 2 were substances that, just as perchlorate, have a potential effect on TSH and T4 levels i.e. nitrate and thiocyanate.

EPA also mentioned that "The researchers state that perchlorate could be a surrogate for another unrecognized determinant of thyroid function".

We would like to comment on the fact that a multitude of other substances exist in the environment that can affect the level of those thyroid hormones and that most probably perchlorate is the surrogate, the marker for this pool of substances and nothing else.

Summary

More than 2 years after the publication of the Blount et al., (2006b) study there exist still doubts and EPA seems to confirm this, that the very low levels of perchlorate, in contrast to the body of literature, would be the cause of the observed thyroid hormone level change.

The following reasoning should eliminate this doubt.

1. Circumstantial evidence

1.1. The effect level found in the Blount study at 10,000 times or 4 orders of magnitude lower than consistently found hitherto in the body of literature is unlikely.

1.2. If it still would be seen as likely, then consequently the current EPA HRL should be divided by 10,000 from 24.5 ppb to 0.002 ppb and even to 0.0002 ppb if an additional UF (uncertainty factor) on top of the NRC UF of 10 would be applied (as has been suggested by some, justified or not).

1.3. Iodine uptake inhibition precedes any adverse health effect of perchlorate exposure including TH (thyroid hormone; here T4 and/or TSH) level change so perchlorate cannot have an effect on TH when there is no iodine uptake inhibition in the first place. Evidence from the NHANES data on which the Blount study was based shows that overall, most probably iodine inhibition did not exist.

1.4. The relationship of 2 other well known iodine uptake inhibitors with TH.

1.4.1. Their "unexpected" relationships Thiocyanate and nitrate show relationships with TH and iodine in an "unexpected" direction and contrary to the perchlorate relationship with TH and iodine which was in the "expected" direction (and then only for iodine insufficient women; the direction was "unexpected" as well for iodine sufficient women).

If those would be assumed to be causal as well - and they should be if the relationship with perchlorate is assumed as such- then the competitive uptake inhibition mechanism as we know it should be discarded and dietary increase of iodine should always be discouraged. The same should be said also regarding the relationship of perchlorate with TH for iodine sufficient women. We have not heard those proposals.

1.4.2. Their strength level The other 2 goitrogens, thiocyanate and nitrate, with the same mode of action as perchlorate do not show this "expected" relationship even though their equivalent levels are 28 and 56 times higher respectively.

Conclusion of 1.4.: If all other relationships found are considered highly implausible(in the opposite direction of what should be "expected") to be causal, what can be the justification to single out one as causal because it seems to fit the "expectations" and explain away all the other relationships as "unclear" since they do not fit those expectations?

2. The number and probability of possible alternative causes

2.1. Why should those possible alternative causes have been considered with priority? Since it was shown that iodine levels overall were probably not relevant we should not look for something that affects NIS (and therefore potentially but only indirectly TH levels) but something that affects TH levels directly.

It is surprising that EPA does not raise this issue but limits itself to mentioning nitrate and thiocyanate. If the Blount et al. study were about iodine uptake inhibition effect then this would have been justified. But it was not.

It was about the downstream effect, the effect on TH.

2.2. Covariates that have not been taken into consideration in the study and should have been so with priority.

There are many widespread contaminants that are goitrogenic with effects on TH levels via mechanisms unrelated to iodine uptake such as organohalogens and other dioxin-like compounds which are ubiquitous and include many pesticides as well.

They act thru different mechanisms.

Only PCBs already include 209 congeners that vary based on the number and positions of chlorine atoms.

Other substances such as Bisphenol-A , methylmercury are believed to be goitrogenic, even halogens like bromide or fluorine added in drinking water (besides chlorine) or their reaction products. Added to these should be natural goitrogenic substances such as isoflavones, genistein, resveratrol, silymarin and linuron.

Data on some were available in the same 2001-2002 NHANES database from which perchlorate, iodine and the other 2 NIS goitrogens were extracted.

Many studies including several EPA sponsored studies deal with those other goitrogens; some even include perchlorate in parallel.

The question should then be asked: why were those goitrogens not controlled for or at least referred to as possible causes?

2.3. The level found compared with the effect level

The known threshold effect level on THs of organo halogens such as PCBs and other dioxin-like substances and their levels in the NHANES 2001-2002 database have been found to be in the same range and some showed a relationship with THs as well.

This is in stark contrast with the 4 orders of magnitude difference for the corresponding levels of perchlorate in the Blount study.

3. What then could be the link between perchlorate and those known endocrine disruptors?

The most obvious and most widely spread common link is chlorine.

On one hand it has been shown that chlorine based disinfectants such as those found in drinking water (DW) oxidize to perchlorate as a disinfection by-product (DBP).

This is for example the reason why Massachusetts doubled its MCL from 1 to 2 ppb.

This oxidation is significant as it corresponds to about 1/3 of the average daily intake of perchlorate according to the Blount study (from the NHANES data).

Bleach is used ubiquitously as for example in water purification stations, paper mills, drinking water and for many other applications.

Other potential sources of perchlorate as a DBP are other chlorine derivates such as chlorine gas and chloramine.

On the other hand other DBPs originate from the reaction of chlorine based disinfectants with organic matter (waste) to form organochlorides.

There are 2 DBP pathways that link perchlorate and those other goitrogenic substances with chlorine:

DBP road 1: Bleach/Cl2/Cl-/chloramine ->ClO-3 ->ClO-4

DBP road 2: (in presence of organic (C) material):

Bleach/ Cl2/Cl-/ chloramine ->phenols ->organochlorides/dioxins

So chlorine is one example of the link between very low levels of perchlorate and TH affecting substances.

Since organo-chlorinated compounds are ubiquitous and since we find around 1/3 of the total dietary perchlorate where we find organo-chlorinated compounds and since many of those have been shown to affect TH levels it is to be expected that low levels of perchlorate are associated with TH levels as found in the Blount study.

Yet assigning cause to this association would be against all common sense as overwhelming circumstantial evidence points in another direction.

Perchlorate seems to be rather a marker, a witness, a messenger of the presence of ubiquitous goitrogenic contamination caused by the net effect of hundreds of substances (see also next section).

4. Would this be the final answer: organochlorides are the sole cause of the (slight) TH changes? Probably not.

There seems to be a ubiquitous contaminant pool in which there are all kinds of goitrogenic substances acting thru all kind of mechanisms that influence TH levels and thyroid function. Somehow they could be all linked together.

So it seems plausible that perchlorate is a marker of this ubiquitous pool of thyroid function affecting contaminants which means that the more perchlorate is found (outside from the point source contaminations of course) the more goitrogenic the pool will be via the chlorine and halogen link and therefore the more goitrogenic effect on THs will be seen.

5. Conclusion

The answer to the question of what caused the Thyroid hormone changes in the Blount study is: all of the above except perchlorate as seen at those very low levels.

It may be felt as politically rewarding to look for a simple explanation but, from what precedes such a simplistic and irrational interpretation would certainly not lead to effective health protective measures. On the contrary it would lead to a feel good situation with only illusory effects.

A careful analysis should precede any sweeping statements like those we are seeing in some media. We hear a lot about holistic approaches in health risk assessment but not many practical applications. This may be one of them.

Comment: In trying to establish a HRL (Health Reference Level) for drinking water, EPA seems to be torn between the 2005 NRC RfD (reference dose) [see reference 1], referred to as "NRC RfD "

hereafter, and a subsequent study [see reference 2], referred to as "Blount" hereafter, that, on first sight, appears to undermine this very RfD.

This study showed a relationship between extremely low levels of perchlorate and TH (thyroid hormone; here T4 and/or TSH) levels.

As a result this relationship has been considered by many as a cause effect relationship suggesting (adverse) effects at a level of perchlorate much lower than that of the NRC RfD, which itself is based on the body of literature.

All kind of erudite and highly complex reviews came out during the following 2 years either supporting or weakening the perceived consequences of this new finding.

Did all this bring us today one step closer to an explanation of this significant contradiction? No, it did not.

Yet it is abundantly clear that there is an evident overall fallacy that has not been exposed. EPA rightly points out, as many have done before, that a cross- sectional study, such as the Blount study can show associations but cannot decide causes.

The main reason is that it does not allow control for non quantified (measured) covariates or for quantified covariates that were not considered relevant but that should have been.

In order to evaluate the likelihood of this hypothetical cause-effect relationship the following 3 aspects should be appraised:

1. The presence of circumstantial evidence i.e. a collection of facts that, when considered together would conclude in favour or against the hypothesis.

2. The number and probability of possible alternative causes.

3. The link of these alternative causes with the hypothetical cause.

Let's see how those 3 obvious criteria work out.

Comment: 1. Circumstantial evidence

1.1. The 4 orders of magnitude difference in levels From Blount (NHANES 2001-2002) data and regression curves, the average urinary level of 2.84 u, which is found to be related to thyroid

hormone (TH) change, is equivalent to an oral perchlorate dose of approximately 0.00004mg/kg-day.

This is 100 times lower than the dose of 0.004 mg/kg-day that was found to be without effect not even on iodide uptake [see reference 1] and which led to the NRC RfD.

Further this dose of 0.004 mg/kg-day on itself is about 100 times smaller than 0.5mg/kg-day, the dose found to have no effect on TH [see reference 1].

So, in stark contradiction to what was found in the body of the literature, the Blount study would suggest, if the relationship perchlorate /TH would be seen as causal, that perchlorate is 10,000 more potent than formerly found.

[see figure in PDF docket ID EPA-HQ-OW-2008-0692-1990]

The following illustrates the effect of 4 orders of magnitude: A dose of perchlorate used to treat Graves disease (excess thyroid function) and which was known since decennia to be effective at about 700 mg/day or 10 mg/kg-day would all of a sudden be effective at 0.001mg/kg-day, a dose that is not only 10,000 times lower than prescribed but also 500 times lower than the dose that only may start to have the intended effect but on euthyroid people instead (0.5 mg/kg- day). At that time would it have been likely that a 10,000 times overdose would have been recommended during several decades knowing that the side effects finally caused this remedy to be pulled from the market? This is highly improbable to say the least.

Another image for the most tenacious readers: To make it more visually comprehensible for their readers, the NRC RfD of 0.0007 mg/l has often been expressed in the media as "a couple of drops in an Olympic seized swimming pool".

The 10,000 times lower dose would then mean that about 9900 swimming pools of that size should be first build in the U.S. before it would be possible to further dilute those same couple of drops to this level since there are only about 100 of those pools existing..

In any case if this first massive conflict would still not be considered relevant or convincing (for reasons that then should be explained however) and the extremely low level causal effect would still be seen as probable then at least the consequences should be consistent which leads us to the second circumstantial evidence:

Response: EPA cannot comment on the calculations by the commenter that have not been peer reviewed.

Comment: 1.2. The new MCL that should be recommended accordingly

This means the RfD and the corresponding MCL (or HRL) should be lowered accordingly and not from 24.5 ppb to, say, 1 ppb (half the Massachusetts MCL, the lowest state MCL) but to 0.24 or 0.024 ppt (if applying an UF of 10 or 100 respectively) or 0.0002 / 0.00002 ppb.

We have not heard this claim. If this causal relationship would nevertheless exist then this corresponding low level should be suggested as an MCL or HRL. Yet the lowest MCL we have seen proposed in relation to this "new finding" was only about 10-50 times lower than the NRC RfD. This shows that even the most enthusiastic believers don't really belief in it.

When it is too bad to believe, it probably isn't.

Besides, since perchlorate is, just as nitrate, also naturally found in many drinking water wells in the US, particularly in the west and centre of the country at levels about 1000 to 10,000 times higher(between 0.1 and 1 ppb) than this "new" level, one wonders then what effect should this have on the TH status of the millions of people in those areas if such much lower levels would have an effect already.

Response: See response to comment ID 20772 under comment code 2200.

Comment: 1.3. A downstream effect implies an upstream effect

Adding even more to this discrepancy was the fact that the NRC RfD was based on an effect upstream from the Blount study effect.

Indeed since iodine uptake inhibition precedes any adverse health effect of perchlorate exposure including TH level change [see reference 1], perchlorate cannot have an effect on TH when there is no iodine uptake inhibition in the first place. This is the essence of the iodine uptake inhibition mechanism leading to a (potential) effect on TH levels.

Unfortunately information about possible Iodine uptake inhibition into the thyroid at such low levels, while highly improbable as shown above, was not available from the NHANES data on which the Blount study was based. - Yet what we do know from those data is that there exists a strong relationship between those low levels of urinary (U) perchlorate and U iodine: for an increase of 1 ug/l U perchlorate, the U iodine levels increase linearly with about 30 ug/l all the way from the first to the ninth decile. So, even if perchlorate would have had a potential effect at such low levels it should have been more than compensated by the iodine association as this is what should be expected from a competitive uptake mechanism and because of the fact that the perchlorate inhibitive potency in relation to iodine is known to be around 1/30 based on in vitro studies [see reference 3] or 1/3 in a recent publication based on a in vivo study [see reference 4].

The scatter plot below [see reference 5] illustrates the strong relationship, all the way to the 9th percentile, of very low U perchlorate with U iodine in the U.S. population (NHANES 2001-2002) controlled for THs.

[see figure in PDF docket ID EPA-HQ-OW-2008-0692-1990]

There may be even an explanation for this: perchlorate and iodine are both naturally present in all soils and low levels of perchlorate [see reference 6] and iodine are continuously formed in the atmosphere (just as the other halogens including iodine [see reference 7] and nitrate by the way). The complete disappearance of the relationship in the 9th percentile could be explained as the appearance of the higher level but less diffuse contaminant point sources of perchlorate on top of this natural background.

- Further the same NHANES data show that U iodine is not related with (serum) TH [see reference 8] which implies that the TH level changes observed seem to be caused by something that does not have anything to do with iodine levels and therefore with iodine uptake inhibition. If the TH levels found are independent from iodine U levels and therefore from the levels present in the diet then the downstream TH changes cannot be caused by an iodine uptake inhibitor such as perchlorate. If that still would be the case then iodine supplements should not be recommended for iodine insufficient individuals; again this does not have any sense.

This association unfortunately was not discussed in the Blount paper as the population was split in 2 groups based on their U iodine levels (this confirms that the mind was set on iodine uptake inhibition and not on any other mechanism, see next section).

Response: See response to comment ID 29078 under comment code 2200 regarding the Blount et al. study. As discussed in the final determination, EPA believes that perchlorate may have an adverse effect on human health.

Comment: What other circumstantial evidence we have?

What about some other covariates?

1.4. Covariates that have been taken into consideration in the Blount study

1.4.1. Relationships of other goitrogens with THs

To be consistent, if the relationship of perchlorate with TH would be considered causal without any supportive evidence then the relationship of the other goitrogens with the same effect on iodide uptake and TH levels should be considered causal as well.

1.4.1.1. Now in this study it was also found that increased levels of thiocyanate were significantly associated with decreased thyroid activity i.e. an unexpected opposite association compared with perchlorate's association. Would that then mean that if this study were about investigating thiocyanate's effect on TH (i.e. not focused on perchlorate) it would have to be concluded that it was now a remedy instead of a goitrogen and that for example consuming cassava would now be good for fighting goitre? Since the opposite is known, this is further strong circumstantial evidence against the causal association.

1.4.1.2. Also nitrate, also a known goitrogen with effect on iodine uptake and therefore, tested (controlled for) as a covariant as well, was significantly associated with T4 levels but only for women with iodine levels considered as sufficient (=100 ug/l) and not for those with levels considered as insufficient. Isn't that contrary to the known mechanism associated with goitrogens as iodine uptake inhibitors? Or how can it be explained that sufficient becomes now insufficient and insufficient becomes now sufficient?

Again the question can be raised: if this were instead a study on the goitrogenic effects of nitrate wouldn't this association, if causal, preclude iodine supplements as a remedy and therefore also preclude iodine as a remedy against perchlorate and thiocyanate? We have not heard this and that would be unlikely and thus further undermines the causal hypothesis.

1.4.1.3. This would then also be in direct conflict with the recommendations we have seen in relation with this study in that iodine insufficient individuals should increase the dietary intake of iodine to compensate for the alleged perchlorate effects.

1.4.1.4. Moreover the fact that perchlorate was associated with T4 also for U iodine sufficient women all the way to the highest levels (besides for iodine insufficient women) would lead to the same contradiction.

1.4.1.5. Most or all of the above statistically significant relationships could only be plausibly causal if the currently generally accepted knowledge about iodine and NIS (Sodium Iodine Symporter) goitrogens in association with the thyroid would be rejected.

We have not found any author bringing forward this new hypothesis about the mechanism related to NIS either.

This overwhelming direct and indirect evidence that the above relationships with other goitrogens could not be causal implies once again that attributing a cause-effect aspect to the perchlorate TH relationship because it happens to be in the "expected" direction, is arbitrary and unreasonable.

Or said in other words, if all other relationships found are considered highly implausible to be causal, what can be the justification to single out one as causal because it seems to fit the "expectations" and explain away all the other relationships as "unclear" [see reference 2] since they do not fit those expectations?

Response: See response to comment ID 29078 under comment code 2200.

Comment: 1.4.2. Levels of other goitrogens compared to perchlorate.

1.4.2.1. Thiocyanate compared to perchlorate The average U level of the goitrogen thiocyanate is 1,200 ug/l which, after applying a potency equivalency of 1/15 [see reference 2,3], translates into 80 ug/l perchlorate equivalency or 28 times more than the average perchlorate level of 2.8 ug/l.

If 28 times more perchlorate equivalent does not show an association in the "expected" direction how could it be explained that 28 times less does?

1.4.2.2. Nitrate compared to perchlorate The average U level of the goitrogen nitrate is 38,000 ug/l which, after applying a potency equivalency of 1/2402, 3, translates into 158 ug/l perchlorate equivalency or 56 times more than the average perchlorate level of 2.8 ug/l.

If 56 times more perchlorate equivalent does not show an association in the "expected" direction as there is interaction with iodine levels but in the "wrong" direction, how could it be explained that 56 times less does?

It should be noted that the perchlorate potency compared to iodine has recently shown to be much weaker in vivo than in vitro yet the relative potency of the goitrogens compared to each other has been shown to remain unchanged [see reference 4].

Conclusion: Circumstantial evidence overwhelmingly concludes against the hypothesis.

Response: EPA does not believe that sufficient data exist to permit comparison of the relative potency of perchlorate to other goitrogens, or to permit the conduct of a cumulative risk assessment. See response to comment ID 29078 under comment code 2200.

Comment: 2. The number and probability of possible alternative causes

2.1. Why should those possible alternative causes have been considered with priority?

Above we have discussed the goitrogens that have the same mode of action as perchlorate i.e. inhibition of iodine uptake thru NIS (sodium iodide symporter).

There exist many other goitrogenic substances (which in effect are also goitrogens as they lead to the same endpoints) that have a different mode of action not related to iodine.

The Blount study is about possible effects on THs of substances present in the population sample. So all known substances that affect TH levels should have been statistically tested and controlled for as well and not only those that act through the same mechanism as perchlorate.

Since as shown iodine levels are probably not relevant we should not look in the first place for something else that affects NIS function (and therefore potentially but only indirectly TH levels) but something that affects TH levels directly.

EPA's current RfD for perchlorate is based on perchlorate's ability to inhibit the thyroid gland's uptake of iodide by competing for the sodium (Na+)/iodide (I-) symporter (NIS), the protein responsible for transporting iodide into the thyroid gland for the purpose of synthesizing thyroid hormones.

So it is surprising that EPA does not raise this issue but limits itself to mentioning nitrate and thiocyanate. If the Blount et al. study were about iodine uptake inhibition effect then this would have been justified. But it was not. It was about the downstream effect, the effect on TH.

Yet in the Blount study it was assumed that iodine uptake inhibition was the upstream effect so much so that, as said, the population had been split into 2 groups, iodine deficient and iodine sufficient. As noted before, this only added more inconsistencies as it exposed additional "unexpected" relationships which should have been seen as an additional warning that something was amiss.

Hence substances that have a direct effect on TH should have been tested with priority instead.

Comment: 2.2. Covariates that have not been taken into consideration in the study and should have been so with priority

We quote from the January 2008 Thyroid journal: "Toxicological models and limited epidemiological studies have indicated that many organohalogen aromatic compounds, including dioxins, polychlorinated biphenyls (PCBs), and polybrominated diphenyl ethers (PBDEs), may be classified as â€˜â€˜endocrine disruptors, as they have the potential to alter normal thyroid function." "Because environmental exposures rarely occur singly, it is often difficult to disentangle a single exposure from other cooccurring environmental exposures and conditions that may confer risks upon children. Therefore, there is often the potential for confounding, in which both the exposure and the outcome under investigation are related to a third factor that may distort the observed exposure-disease relationship." "In epidemiologic studies, it is critically important to identify, measure, and control for such confounders."

As mentioned, there are many widespread contaminants that are goitrogens with effects on TH levels via mechanisms unrelated to iodine uptake.

Some can be expressed as TEQ's (total toxic equivalents) and include the known endocrine disruptors such as PCBs (polychlorinated biphenyls), PCDDs (polychlorinated dibenzo-pdioxins), PCDFs (polychlorinated dibenzofurans) besides PCDFs, PBDEs (polybrominated diphenyl ethers), DDE (dichlorodiphenyldichloroethylene) TCDDs (tetrachlorodibenzo-pdioxin), TBBPAs (Tetrabromobisphenol A), degradation products of DDT such as HCB (Hexachlorobenzene), etc. [see reference 9, 10 ,11]

Most of them have a structure resembling thyroid hormones [see reference 12].

They act thru different mechanisms [see reference 13].

PCBs include 209 congeners that vary based on the number and positions of chlorine atoms. Compared with estrogens and antiandrogens, thyroid-disrupting chemicals are the least well studied endocrine disruptors (ED). It is therefore not surprising that few mixture studies exist using this kind of agents.

Further many other substances with completely different structures are known goitrogens in the sense that they also affect directly or indirectly TH levels (see section 4).

Question: Why weren't these substances tested and controlled for as covariates to evaluate the independence of the perchlorate relationship, the more so that the data on some, such as PCBs and other dioxin-like substances, including those concerning pesticides, were available as they were included in the same 2001-2002 NHANES database from which perchlorate, iodine, the other 2 NIS goitrogens and other 12 tested covariates were extracted?

here were other hints that pointed to a different direction: While NHANES 2001-2002 THs levels do not reflect urinary iodine concentrations [see reference 5], serum PCBs, p,p'-DDE and HCB predict Thyroid Hormone Levels [see reference 14] and some do so in NHANES 2001-2002 as well [see reference 15] Also co variants such as smoking status which were associated with thiocyanate in the Blount study and follow-up studies [see reference 16] could just as well be linked to organohalogens as cause since tobacco contains organohalogen pesticides that are organohalogen based or transformed in such substances during burning [see reference 17].

Also why doesn't EPA itself refer here to those critical covariates as they did in the EPA coauthored document: Moving Upstream: Evaluating Adverse Upstream Endpoints for Improved Risk Assessment and Decision-Making, EHP, 2008 and other EPA studies? [see reference 18, 19, 20].

Also reference [see reference 12] that dealt with perchlorate and PCBs as EDs together was research sponsored by an EPA grant.

Why would for example investigating the effects on TH levels of a certain pesticide in soya without controlling for say isoflavones (see further below) or vice versa not be acceptable and why would it be in the case of perchlorate, particularly at such extremely low levels.

Response: The hypothesis tested for in the Blount study was that there was a relationship between perchlorate and a limited number of other goitrogens, iodide status, and TSH/T4 concentration in the samples evaluated. The additional analyses noted by the commenter are beyond the scope of the Blount study. EPA relies upon the best available peer reviewed data. See response to comment ID 21049 under comment code 2200.

Comment: 2.3. The level found compared with the effect level

The known threshold effect level on THs of organo halogens such as PCBs and other dioxin like substances that has an effect on THs has been found to be in the range of 0.1 to 10 ug /l serum depending on the substance [see reference 21].

The levels of those substances found in NHANES 2001-2002 is in this range and, as mentioned, a relationship of some with THs was found as well [see reference 15].

This is in stark contrast with the 4 orders of magnitude difference between the effect level of perchlorate on THs known from the body of the literature and the perchlorate levels that were related with THS found in the Blount study.

This is illustrated by some scatter plots [see reference 5]:

Scatterplot 1 and 2: the sum of 24 PCBs [see reference 5] has a similar relation with TSH as does perchlorate and for the same range of concentrations (The PCBs are concentrated at the left because of the detection limit). The 2 relationships are statistically significant.

[see figures in PDF docket ID EPA-HQ-OW-2008-0692-1990]

Response: EPA cannot evaluate calculations presented by the commenter that have not been peer reviewed.

Comment: 3. What then could be the link between perchlorate and those known endocrine disruptor.

The most obvious and most widely spread common link is chlorine. On one hand it has been shown that chlorine based disinfectants such as those found in drinking water (DW) oxidize to perchlorate as a disinfection by-product (DBP).

This is for example the reason why Massachusetts doubled its MCL from 1 to 2 ppb because otherwise chlorination of DW and swimming pools with for example bleach would have to be curtailed.

Is this oxidation of perchlorate from bleach (hypochlorite and hypochlorous acid) significant in comparison with daily intake of perchlorate?

According to the Blount study (from the NHANES data) the average urinary perchlorate level in the population is 2.84ug/l which is roughly equivalent to an oral dose of 0.04 ug/kg-day. This corresponds with drinking water of 1.4 ppb. Massachusetts' MCL was based on data that showed that about 0, 5 ppb perchlorate originated from bleach alone [see reference 22].

Therefore about 1/3 of the average daily intake of perchlorate would be due to bleach oxidation alone which is substantial and which shows that chlorine could be a significant source of perchlorate.

Bleach is used ubiquitously as for example in water purification stations, paper mills, drinking water and for many other applications.

Other potential sources of perchlorate as a DBP are other chlorine derivates such as chlorine gas and chloramine.

On the other hand other DBPs originate from the reaction of chlorine based disinfectants with organic matter (waste) to form organochlorides [see reference 23].

What could be one of the possible pathways that link perchlorate to organochlorides such as PCBs via chlorine?

According to EPA the building block for organochlorides is chlorophenol and chlorophenols are produced from the organic matter found in used water when it reacts with chlorinated disinfectants [see reference 24] (phenol is benzene with a hydroxyl group and PCBs are basically 2 chlorinated benzene rings).

Those DBPs are found back in the drinking water leaving the water purification plants just as perchlorate when no special perchlorate removing devices are used which is the case most of the time in areas where only low levels are found.

So this is one example of the link between very low levels of perchlorate and TH affecting substances: chlorine based disinfectants such as bleach, Cl2 and chloramines evolve to perchlorate on one side and to phenols, PCBS and other organochlorides including dioxin-like compounds on the other side.

[Chloramines, besides being an added disinfectant, can also be formed as a reaction product of bleach with ammonia, itself amply present in used water [see ref 25]].

Response: EPA discussed the potential for perchlorate to be introduced into drinking water as part of the May 1, 2007 FR Notice. However, the source of perchlorate contamination is not a key factor in the determination under SDWA to regulate a contaminant. The presence of perchlorate in disinfectants will be a factor evaluated by EPA as part of the treatment and technology evaluation for the proposed NPDWR for perchlorate.

Comment: Summary of chapter 3

DBP road 1: Bleach/Cl2/Cl-/chloramine ->ClO-3 ->ClO-4

DBP road 2: (in presence of organic (C) material):

Bleach/ Cl2/Cl-/ chloramine ->phenols ->organochlorides/dioxins

Since organo- chlorinated compounds are ubiquitous and since we find at least 1/3 of the total dietary perchlorate where we find organo-chlorinated compounds and since many of those have been shown to affect TH levels it is to be expected that low levels of perchlorate are associated with TH levels as found in the Blount et al study.

Yet assigning cause to this association would be against all common sense as overwhelming circumstantial evidence shows in another direction.

Perchlorate seems to be rather a marker, a witness, a messenger of the presence of ubiquitous goitrogenic contamination caused by the net effect of hundreds of substances (see also next section).

This alternative explanation would on the same time eliminate any and all contradictions as listed from section 1.1. to 1.4.2.2 above.

Response: EPA does not believe there are sufficient scientific data currently available to assess and characterize the combined risk of goitrogenic compounds. EPA has committed to a drinking water strategy that outlines four principles to expand public health protection for drinking water (USEPA, 2010b). One of these principles is to address contaminants as groups. However, EPA does not believe that regulatory action to address perchlorate should be further delayed. Therefore, EPA intends to develop a proposed rule for perchlorate. At such time as a NPDWR is promulgated, EPA is required to review and revise, as appropriate, its drinking water standards at least every six years. Any revision must at least maintain or improve public health protection. When there are sufficient scientific data to assess the cumulative risks of perchlorate and other contaminants, EPA will review this information to evaluate whether any revisions of NPDWRs are appropriate.

Comment: 4. Would this be the final answer: organochlorides are the sole cause of the (slight) TH changes?

Probably not.

The fact that in the NHANES 2001-2002 database organochlorides are cross- sectionally associated with THs and, contrary to perchlorate, at levels that are consistent with known effect levels and, contrary to perchlorate, that this does not occasion related inconsistencies if the relationship would be seen as cause effect, still does not mean it is so.

What we only can say at this point is that the chance that those contaminants are at least partially the cause is much higher than for perchlorate.

There seems to be a ubiquitous contaminant pool in which there are all kinds of goitrogens acting with all kind of mechanisms that influence TH levels and thyroid function.

Somehow they could be all linked together.

Following an example of such a link:

When bromides are used as disinfectant also organobromides are formed [see reference 21].

When bromine and chlorine is involved, halogenated furanones can be produced in drinking water by the reaction of naturally occurring organic matter and bromide with the disinfectant chlorine and chloramine. Research on their concentrations in drinking water is at an early stage and they are not regulated by EPA: http://pubs.acs.org/cen/news/86/i13/8613news7.html

[Clarification: A furanone is a furan where the H is substituted with Cl, becoming polychlorinated furanones or polychlorinated dibenzofuranones. A furan is short for dibenzofuran; a chlorinated dibenzofuran is a PCB with a furan ring in the middle]

So the halogen bromine can join the second pathway for chlorine: Bleach/Cl2/ Cl2/Cl-/ chloramine, bromides ->furanones or phenols ->organohalogens/dioxins

This can be illustrated again thru NHANES data plots:

Scatterplot 3 and 4 [see reference 5]: the organobromide PDE (polybrominated diphenyl ethers) has a similar relation with TSH as does perchlorate and for the same range of concentrations. The 2 relationships are statistically significant. Thus organochlorides, organobromides and perchlorate seems to be related with each other within the goitrogenic pool.

[see figures in PDF docket ID EPA-HQ-OW-2008-0692-1990]

Some components of this goitrogenic contaminant pool have a stimulatory or agonistic effect, others an inhibitory or antagonistic effect [see reference 26, 27]. Some do not have any effect at all at environmental doses.

This may explain why in cross sectional studies as those based on the NHANES data base the effect of the sum of some PCBs apparently is not always greater than each individual effect as would be expected [see reference 28] as each individual PCB on itself can be linked to other non identified and quantified goitrogens i.e. (once again) not controlled for covariates with opposite effects.

As mentioned, already there exist 209 known congeners of PCBs alone. They vary based on the number and positions of chlorine atoms but also on their effect (strength and direction).

Many have not even been studied on their goitrogenic effect.

Even different groups of chemicals with different mechanism could have synergetic or antagonistic effects [see reference 29].

Others may be linked to each other in certain environments and not in others.

Going back to the example above: Polychlorinated Biphenyls (PCBs) and Polybrominated Diphenyl Ethers (PBDEs) (both also called polyhalogenated phenolic compounds) may have a cumulative effect where bromine and chlorine based disinfectants are used (for example for swimming pools) and end up as DBPs (disinfection byproducts) in drinking water after having gone thru the purification plant. This link could not exist in places where one of both is not used.

Other goitrogenic phenols, such as Bisphenol A, linked itself to polyvinylchloride (PVC) such as used in waterpipes, may be linked to this chloride and halogen pool. On the other side completely different types of goitrogens, even natural ones, could be linked indirectly to the pool as well: for example organohalogen based pesticides may be present in very low amounts in soybeans but the goitrogenic effect could instead be primarily due to the isoflavones naturally present in soymilk [see reference 30] or the thiocyanates present in rape or broccoli or other natural goitrogens such as genistein, resveratrol, silymarin, linuron [see reference 24].

Also fluorine is considered a goitrogen [see reference 31]. So, adding fluorine in salt for dental purposes could partially neutralise the effect of added iodine. Adding fluorine, another halogen, in drinking water, which is also common, would then on itself be linked to perchlorate and the organohalogen DBPs.

Further fluorine is a major constituent of phosphate fertilizers [see reference 32] and is taken up by the crop so it could, just as the goitrogenic pesticides and isoflavones, be part of the goitrogenic pool as well. Also iodine itself, the fourth halogen, is used as a disinfectant.

Other factors, even the most unexpected (birth delivery mode) may confound the effects [see reference 33].

So it seems plausible that perchlorate is a marker, but only marker, of this ubiquitous pool of thyroid function affecting contaminants which means that the more perchlorate is found (outside from the

point source contaminations of course) the more goitrogenic the pool will be via the chlorine and halogen link and therefore the more goitrogenic effect on THs will be seen.

The answer to the question of what caused the Thyroid hormone changes in the Blount study is: all of the above except perchlorate as seen at those very low levels.

Comment: It may be felt as politically rewarding to look for a simple explanation but, from what precedes, such a simplistic and irrational interpretation would certainly not lead to effective health protective measures. On the contrary it would lead to a feel good situation with only illusory effects.

A careful analysis should precede any sweeping statements like those we are seeing in the media. We hear a lot about holistic approaches in health risk assessment but not many practical applications. This may be one of them.

Comment: iv. Blount et al. (2006; cited at Blount et al., 2006b in the EPA Notification)

Using the NHANES 2001-2002 data set and a cross-sectional study design, this study reports measurement of urinary perchlorate, urinary iodide, serum TSH, and serum total T4 levels in men and women over the age of 12. The 2001-2002 NHANES data provide the largest group of subjects to date from which sampling data can be derived. The authors report that perchlorate levels were not associated with total T4 or TSH levels in men, but were a negative predictor of total T4 and a positive predictor of TSH in women with urinary iodine less than 100 ug/L. They report that in women with urinary iodine greater than 100 ug/L, urinary perchlorate was a positive predictor of TSH, but not associated with T4. The significance of evaluating women with urinary iodide less than 100 ug/L is based on the WHO statement that a median urinary iodine concentration for the entire population, based on spot samples of less than 100 ug/L is indicative of overall iodine deficiency for that population (WHO 2004).

This study has drawn a great deal of attention as it appears-to the average audience-to demonstrate an "effect" of perchlorate, albeit at exposures below those which cause any measurable inhibition of iodide uptake. However, there are a number of considerations that should be noted that to better understand the significance of the data reported.

Comment: Second, it is important to understand what the methods inherent to scientific research are. For example, knowing what is meant by "statistical significance and "clinical significance." A "statistically significant" difference simply means it is unlikely that there is a difference between two variables (e.g., numbers) that is due to chance. With a well designed experimental study, statistical significance can be extremely important. However, statistical significance is also a function of sample size, variability in the variables measured, etc. Statistical significance does not necessarily mean the difference is large, important, or biologically significant. However, for biological data, we are keenly interested if something is statistically significant is it also clinically significant, that is is there change in the variable or parameter that is large enough to affect a clinical or medical condition (e.g., development of hypothyroidism). Blount et al., 2006 report statistically significant variables, but do not report any variables with clinical significance.

This type of study conducted by Blount and his colleagues cannot determine causation, only association between the variables studied (Wartenberg and Buckler, 2001). If important variables are missing, then spurious conclusions can be made. Thus, without a full set of variables measured, including a consistent urinary iodide measurement, any association should be examined carefully for reliability.

Furthermore, perchlorate did not actually lower (or was even associated with) thyroid hormones outside the normal range of values. Even if it had, the NRC committee does not think that "...transient changes in serum thyroid hormones or TSH concentrations are adverse health effects; they are simply biochemical changes that might precede adverse effects" (NRC, 2005).

The study was considered by ATSDR; however, ATSDR states, "limitations of the study acknowledged by the investigators include those common to cross-sectional analyses, the assumption that urinary perchlorate correlate with levels in the thyroid stroma and tissue, and the measurement of total T4 rather than free T4" (ATSDR, 2008).

Third, any study must have careful consideration for the parameters and variables that are measured or available. The purpose of NHANES is designed to collect information about the health and diet of people in the United States. It is a survey for a broad range of possible diseases related to diet and health. While it obtains parameters for thyroid function, those parameters fall far short of the parameters needed to clearly understand thyroid health. For example, there were only two measures of thyroid function (total T4 and TSH) in the NHANES dataset used in this study; NHANES currently uses spot urine samples for iodide status which are neither the preferred, nor most reliable,

measure of urinary iodide (Barr et al. 2005); there was lack of normalization for the dilution of individual urine samples using urinary creatinine levels; and due to restraints of the NHANES database, the authors were not able to note the incidence of autoimmune thyroiditis, the most common thyroid disorder in the U.S., which causes changes in serum T4, T3, and TSH concentrations due to errant immune mechanisms attacking the thyroid gland (NRC, 2005). A complete assessment produced by Intertox is attached as Appendix A. In the appendix, there is a more thorough discussion regarding the use of spot urine testing, confounders, and use of the available NHANES variables to drawn conclusions.

This study did not present urinary measures normalized to creatinine. The concentration of dissolved substances in urine, such as iodide, may vary between individuals or between samples from the same individual. Normalization with creatinine is not a perfect method, but is commonly used to account for this variability (Furnee et al. 1994).

Comment: At a recent symposium on perchlorate held in conjunction with the annual Society of Toxicology (SOT) meeting in Seattle, Lamm et al. (2008) presented their initial reanalysis of the NHANES dataset used by Blount et al. with an adjustment for urinary creatinine. Lamm et al. considered a subset of women from the Blount et al. study who were of childbearing age (15-44 years old; the Blount et al. study group included all women over the age of 12) as well as the interaction of thiocyanate and nitrate, both in urine. They found there was no significant association between perchlorate and total T4, even for women with urinary iodide less than 92 ug/g (Figure 2). They did find a significant association for women with urinary iodide greater than 163.7 ug/L for both perchlorate and thiocyanate.

Comment: The American Thyroid Association (ATA) issued a public health statement cautioning against the paper's use in making decisions on regulating perchlorate. The ATA noted that "serum thyroxine was measured as total thyroxine rather than as free thyroxine, the most frequently used clinical measurement and the physiologically available form of thyroxine. Thyroid autoantibodies, an

important confounder in thyroid physiology, have not yet been measured. These have an especially high prevalence in women and may have contributed to the reported correlations. The presence of potentially confounding pharmaceutical and medical factors, such as estrogen use or autoimmune thyroid disease, was not used as a basis for exclusion from the analysis. Inclusion of laboratory results from multiple laboratories may need to be more carefully considered. The reason that perchlorate, but no other measured goitrogen studied, influenced thyroid function at low urinary levels of iodine is not explained. The development of further laboratory information is necessary before the implications of the findings can be understood. The issues raised are important and additional study to resolve them should be pursued" (ATA, 2006).

Fourth, not only were the thyroid hormone values within normal clinical ranges, but urinary perchlorate levels as a surrogate for dose demonstrate that these perchlorate exposures are well below the threshold for zero inhibition of iodide uptake, a non-adverse effect. Exposures that are below the threshold for iodine uptake inhibition are below the NOEL for perchlorate and are not adverse (NRC, 2005; Greer et al., 2002).

Finally, taken from the premise that science is incremental and knowledge builds collectively over time, concerns raised by scientists related to the Blount et al. study should be considered an opportunity for further study. According to Dr. Benjamin Blount, a new study will be conducted using a new data set, NHANES 2007, and will include obtaining data for eight variables of thyroid function (total T4, free T4, total T3, free T3, thyroid globulin, anti-thyroid peroxidase, anti-thyroid globulin, and TSH).[FN5: Personal Communication between Dr. Richard Pleus and Dr. Benjamin Blount. September 22, 2008.] Furthermore, recognizing that urinary spot iodine or single point iodine measures are not a good indicator of iodine status, a different approach is being considered. We believe more research should be conducted to better understand the results of this study.

Comment: Steinmaus et al. (2007) used the same dataset as Blount et al. to assess the correlation between smoking, thiocyanate and urinary perchlorate, and thyroid hormone levels. Using the same NHANES data set, it is not surprising that many of the same results were noted. Many of the same methodological issues reported for Blount et al. apply to this study. As in Blount et al., they did not find any interaction between perchlorate and smoking and TSH or total T4 in women with urinary iodine levels greater than or equal to 100 ug/L or in men. They did conclude that in women with urinary iodine less than 100 ug/L, perchlorate increased the risk of lower total T4 and greater TSH, just as was reported in the Blount et al. study. This association was stronger when the woman was also a smoker or had high urinary thiocyanate levels.

Both Blount et al. and Steinmaus et al. (2007) show an association between exposures to low, environmentally-relevant levels of perchlorate and non-adverse reductions in thyroid hormones that remain within the normal ranges. However, these studies contradict the wide body of direct studies showing no effect even at low levels. These studies are valuable in that they test a large population;

however, neither study shows that exposure to perchlorate at environmentally relevant doses causes an adverse health effect, even in a sensitive population.

Response: See response to comment ID 29078 under comment code 2200. As discussed in the final perchlorate regulatory determination and elsewhere in the response to comments document, EPA believes that perchlorate may have an adverse effect on the health of persons.

Comment: v. Blount et al. (2007)

Blount and colleagues used the NHANES urinary perchlorate data to estimate the total daily dose for adults. These data were adjusted for creatinine. The estimated 95th percentile dose was 0.234 ug/kg-day with a confidence interval of 0.202 - 0.268 ug/kg-d. They also reported that perchlorate was measurable in all of the samples they tested and the urinary levels were higher in children compared to adults. The estimated doses reported here were lower than the RfD and below the level of inhibition of iodide uptake. The NRC states that "...inhibition of iodide uptake by the thyroid clearly is not an adverse effect; however if it does not occur, there is not progression to adverse health effects" (NRC, 2005).

Comment: APPENDIX A

Review of Blount BC, Pirkle JL, Osterloh JD, Valentin-Blasini L, Caldwell KL. 2006.

Urinary perchlorate and thyroid hormone levels in adolescent and adult men and women living in the United States. Environmental Health Perspectives 114(12):1865-71.

A number of scientific issues related to the experimental design of the NHANES dataset and the Blount et al. (2006) analysis make drawing meaningful conclusions from the data extremely difficult. Many of these issues are discussed below, although this list is not exhaustive.

In their paper, Blount et al. (2006) examined the relationship between urinary levels of perchlorate and serum levels of thyroid stimulating hormone (TSH) and total thyroxine (T4) in men and women, aged 12 and older, participating in the NHANES during 2001-2002. They made the following primary observations:

* Perchlorate was not a significant predictor of total T4 or TSH levels in men.

* For women with spot urinary iodine concentrations < 100 ug/L, perchlorate was a significant negative predictor of total T4 ($p < 0.0001$) and a positive predictor of TSH ($p = 0.001$).

* For women with urinary iodine >= 100 ug/L, perchlorate was a significant positive predictor of TSH ($p = 0.025$), but not total T4 ($p = 0.550$).

To assess the reliability of these conclusions, we reviewed the Blount et al. (2006) paper and the NHANES 2001-2002 dataset (CDC 2006) used by the authors. We reviewed the same variables reported in the paper and several dozen other variables not reported in the paper but reported in the NHANES 2001-2002 dataset.

The data collected by NHANES is a survey and not a true epidemiological or clinical study. In epidemiological and clinical studies, effort is made to design the study to control for all variables except the variables in question. Surveys are not designed in this manner-their purpose is to collect data from a large number of people over a period of time. NHANES is designed to assess the health and nutritional status of adults and children in the United States (U.S.), combining interviews and physical examinations. It is a major program of the National Center for Health Statistics (NCHS), which is part of the Centers for Disease Control and Prevention (CDC) of the U.S. Public Health Service, and has the responsibility for producing vital health statistics for the nation (CDC, 2006).

NHANES 2001-2002 was designed to continue the collection of information about the health and diet of people in the U.S. that was begun with earlier surveys to fulfill specific goals. These include estimating the number and percent of persons in the general U.S. population and designated subgroups with selected diseases and risk factors; monitoring trends in the prevalence, awareness, treatment, and control of select diseases; monitoring trends in risk behaviors and environmental exposures; studying the relationship between diet, nutrition, and health; and exploring emerging public health issues.

Comment: Key components to designing a thyroid study

When conducting a thyroid study, a number of key variables should be considered that are not necessarily included when collecting data for a survey such as NHANES. For instance, thyroid hormone and TSH levels can vary substantially during the day. Free T4 (not total T4, which was measured in NHANES) is the most important thyroid parameter for assessing hypothyroidism. Because hypothyroidism is most commonly caused by one's own immune system, parameters used to assess this effect (including serum antibodies to thyroglobulin and thyroid peroxidase) should also be measured (but were not in the NHANES study). In general, the use of NHANES data to draw

conclusions regarding exposures is controversial because of "...the utility of these data to address an existing public health concern, including investigation of etiology, instead of undertaking a study that includes original data collection" (Wartenberg and Buckler, 2001).

Comment: Study variables of concern

We were able to confirm the dataset Blount et al. (2006) used in the paper and generally replicate the statistical results obtained by Blount et al. This allows us to examine the experimental design of the study with more confidence. Based on our review, we observed several key variables that caused us to question the conclusions presented in the Blount et al. paper. These variables are summarized below.[FN10: This evaluation is primarily based on the sample of 1,111 women aged 12 and older (i.e., the "study group"), described by Blount et al., from whom urine samples for perchlorate and serum thyroid hormone/TSH concentrations were measured, and excluding those who had a reported history of thyroid disease, were taking thyroid medications or a small subset of other thyroid- active drugs, or had extreme (high) levels of TSH or extreme (low) levels of T4. It should also be noted that total T4 measurements were performed at two separate laboratories which may have introduced some bias.]

Relying upon the urinary iodide measurements for classification of study subjects into "low" or "high" iodine groups is not scientifically appropriate.

* Urinary iodine concentrations in the study group ranged from 6 to 136,161 ug/L. The geometric mean was 127 ug/L (SE = 5.4) and the 5th and 95th percentiles were 22 and 568 ug/L, respectively. Our findings for this group are consistent with the summary of urinary iodine measurements in NHANES 2001-2002 published by the CDC (Caldwell et al., 2005). If taken at face value as representative of chronic iodine nutrition, the upper limits of these measurements likely exceed safe levels and should be a source of some alarm for the CDC. For example, elevated TSH levels and hypothyroidism have been associated with daily iodine intakes in excess of 750 ug/day by adults (NAS 2001). However, these measurements were taken in spot samples and are thus not necessarily indicative of an individual's iodine status.

* Urinary creatinine concentrations were highly variable from subject to subject (range 9 to 774 ng/mL), indicating significant differences in sample dilution and, likely, urinary output.

* The WHO has stated that a median urinary iodine concentration within a population, based on spot samples of <100 ug/L is indicative of iodine deficiency within the population (WHO, 2004). The median urinary iodine concentration for the study population evaluated by Blount et al. (n =1,111) is 133 ug/L. Thus, assuming that iodine deficiency exists within this population is inappropriate- the WHO criteria are not meant to diagnose iodine deficiency in individuals (Borak, 2005). Conversely, the best way to establish individual urinary excretion of iodine (or any urinary

analyte) is to collect 24-hour samples (Bourdoux, 1998). However, without a reliable measure or indicator or iodine status, comparison s make suing this measure could be spurious.

* Figure 1A illustrates the variability in urinary iodine concentrations in the Blount et al. dataset.

[Figure 1A: Variability of Urinary Iodine from Blount et al. (2006) - See PDF Docket ID EPA-HQ-OW-2008-0692-1855]

Response: See response to comment ID 29078 under comment code 2200. EPA does not have sufficient information to evaluate the WHO criteria for iodide status.

EPA Comment Code: 2200

Comment: 1. Characteristics of individual members of the study group vary widely. Because many of these variables could impact overall subject health and, potentially, thyroid hormone or TSH levels, it is impossible to establish causality based on this dataset. The following is a sample of some of these variables-many others, both reported in and not reported in the dataset, could potentially impact thyroid measurements.

* NHANES is a survey designed to assess the health and nutritional status of adults and children in the U.S. It is not a controlled epidemiological study. Up to 3,400+ different variables are reported in the online NHANES 2001-2002 dataset in association with specific study subjects. The potential for spurious associations between variables is significant.

* 48% of those who responded were active smokers (42% reported smoking "everyday" and 6% "some days"; only 301 subjects out of 1,111 study subjects had a reported response to this question). 21% of smokers reported smoking 15 or more cigarettes per day. Smoking status of study subjects under 18 years of age (29% of all study subjects) was not reported due to privacy concerns. In addition, 21% of study subjects reported living in a home with a smoker. Smoking is a known source of thiocyanate and other goitrogens. In smokers, cyanide from cigarette smoking is likely the most important source of SCN- in the body (Tonacchera et al., 2004). Ingbar (2000) states that thiocyanate as well as the pyridine components of cigarette smoke are likely a cause of lower T4 and T3 levels in serum of heavy smokers. Smoking and thiocyanate were found to be significant in a later analysis of the same data (Steinmaus et al., 2007).

* 105 reported being pregnant at the time of the examination. Pregnancy is known to have an effect on thyroid economy with significant changes in iodine metabolism and serum thyroid binding proteins (Lazarus, 2005a; 2005b).

* Although Blount et al. excluded subjects who were taking thyroid medications (e.g., levothyroxine) or certain other thyroid active agents (e.g., propylthiouracil or methimazole), subjects taking any other kind of drug were included. 43% of study subjects reported taking at least one prescription drug within the month preceding their examination interview. This includes subjects taking

medications known to directly affect the thyroid including lithium, amiodarone, and carbamazepine. Many drugs affect tests of thyroid function through alterations in the synthesis, transport, and metabolism of thyroid hormones, as well as via influences on thyrotrophin (TSH) synthesis and secretion. Despite effects on circulating thyroid hormone and TSH levels, few drugs result in important changes in clinical thyroid state, but difficulty in interpretation of thyroid function tests often results. Commonly prescribed drugs including anticonvulsants, non-steroidal anti-inflammatory drugs, steroid hormones and heparin may result in abnormal thyroid function tests in the absence of clinical features of thyroid dysfunction. In contrast, lithium and iodine containing drugs, including radiographic contrast agents and amiodarone, may result rarely in overt thyroid disease (Davies and Franklyn 1991; Gittoes and Franklyn 1995; Wenzel 1996; Daminet and Ferguson 2003).

* Many reported having one of a number of specific potentially severe medical conditions; however, only a limited list of conditions was reported. For example, 14 reported having had heart failure, 3 had a current liver condition, 71 had current or past cancer, 13 had been told at some time they have weak or failing kidneys, and an unreported number (due to privacy concerns, presumably) had hepatitis C. Kidney failure is known to causes alterations in thyroid hormone metabolism known as nonthyroidal illness syndrome (Rosolowska-Huszcz et al., 2005). Hepatitis C patients on interferon therapy were found to be more susceptible to autoimmune thyroid diseases (Muratori et al., 2005).

* 4% of adult study subjects are underweight (per CDC guidelines, BMI <18.5), 20% are obese (BMI >=30 and <40), and 4% are morbidly obese (BMI >= 40). Associations between body weight and thyroid hormone and TSH levels have been reported in obese and morbidly obese individuals (Sari et al., 2003; Michalaki et al., 2006).

* Many report other types of exposures. 16% of study subjects reported using pesticides within their home during the previous month. A small number of women (16) reported using cocaine or other street drugs within the previous year, with one reporting using a drug on a total of 200 days during the previous year- because of the nature of this information, it could be assumed that this statistic is 28 underreported. Illicit drug use status for subjects under age 18 was not reported. Associations between pesticide exposure and changes in thyroid hormone/TSH levels have been reported in some animal studies (Beard and Rawlings 1999; Jeong et al., 2006). T4 levels have been shown to decrease in rats following amphetamine administration (Budziszewska et al., 1996).

* 66% of study subjects reported regularly (five or more times per month) consuming dark leafy green vegetables. Among these, consumption amount varied widely (up to 91 times per month). 48% reported consuming cooked dried beans or peas five or more times per month. Dark green vegetables from the Brassica family (e.g., broccoli, kale) are known to contain high concentrations of both thiocyanate and nitrate, two agents known to cause iodide uptake inhibition (IUI) by the thyroid in the same way as perchlorate. Legumes are also known to contain high concentrations of nitrates.

* 46% of study subjects reported taking dietary supplements during the month preceding their examination interview. 2% (22 subjects) admitted taking a dietary supplement during the fasting period. There is evidence that dietary supplements can affect thyroid function. For example, short-term dietary supplementation with kelp (high in iodine) significantly increases both basal and poststimulation TSH (Clark et al., 2003).

* NHANES 2001-2002 does not report on consumption of soy or soy products. Soy consumption has been associated with development of goiter and an increase in TSH levels in humans (Doerge and Sheehan, 2002). Soy products are heavily marketed to women as healthful, including such products as soy milk, tofu, energy bars and drinks, and meat substitutes. Soy isoflavones (e.g., genistein and daidzein) can also be measured in biological samples such as serum, to give an approximation of soy intake levels.

* Several other important study variables, including location and time of year when samples were collected, were not reported due to privacy concerns. Seasonally-related changes in thyroid hormone concentrations have been shown in adults, with higher T3 and T4 values seen in winter months, and a tendency to a greater TSH response to TSH-releasing hormone (TRH) was noted at this time (Harrop et al., 1985). These changes could reflect a centrally-mediated response of the hypothalamic-pituitary-thyroid axis to environmental temperature (Harrop et al. 1985). Significant annual, four-monthly and biannual rhythms were detected in serum TSH in adults, with the lowest detected in spring. A significant annual rhythm was detected in T3, with lower values in spring and summer than in the other seasons. The peak-trough differences in the yearly variation expressed as a percentage of the mean were 29.1% and 8.2% for TSH and T3, respectively (Maes et al., 1997).

EPA Comment Code: 2200

Comment: 2. The "spot" urine and serum samples cannot be relied upon to establish chronic exposure levels or conditions. Spot samples are known to be inherently variable due to variations in urine volume and intake of exogenous compounds, and, in this population, fasting times varied widely between individuals and a substantial percentage of participants did not comply with study fasting requirements.

* For chemicals with a short biological half-life (e.g., perchlorate, iodine), concentrations in spot urine samples are known to be highly variable between samples, due to within- and between-day variations in urine volume and intake of exogenous compounds (Barr et al., 2005). Factors shown to influence concentrations include fasting time, time of day, nature of the last meal, sample dilution, collection method, preservation method, sample interferences, and analytical method (Rasmussen et al., 1999). Urinary iodine concentrations in 24-hour samples vary up to three fold from one day to another. This suggests that a single sample is insufficient to determine long-term iodine status (Rasmussen et al., 1999). Population iodine excretion estimates require 100 to 500 spot urine samples for each group or subgroup and fewer than 10 urine samples in an individual may be misleading (Anderson et al., 2008).

* Serum and urine samples were collected at either "morning" (46%), "afternoon" (36%), or "evening" (18%) examination sessions. Specific sample time of day is not given. In humans, serum TSH concentrations are at their maximum at night, shortly before sleep, about 50-100% greater than the morning low (Fisher, 1996). Early morning values are greater than later morning values (Surks et al., 2005). TSH is secreted in pulses, with eight to fourteen pulses occurring in 24 hours. Sleep

deprivation, strenuous exercise, or working during night or evening shifts accentuate the rhythms (Surks et al., 2005).

* Fasting times were highly variable. Subjects appointed to a morning session were asked to fast for 9 hours while subjects appointed to an afternoon or evening session or a home exam session were asked to fast for 6 hours. However, the protocol states the "greater goal [is] completing as many components as possible within the time constraints of the session with phlebotomy as the highest priority component." Reported length of fast ranged from 0 to 63 hours, with a mean and 50th percentile of 10.3 hours and 5th and 95th percentiles of 1.7 hours and 19 hours, respectively. For the morning, afternoon, and evening sessions, 8%, 13% and 24%, respectively, did not meet the fasting requirement.

* About 2% (22/1111) admitted taking a dietary supplement during the pre-blood and urine collection fasting period. There is evidence that dietary supplements can affect thyroid function. For example, short-term dietary supplementation with kelp (high in iodine) significantly increases both basal and poststimulation TSH (Clark et al., 2003).

* Study participants were allowed to consume diet soda, black coffee or tea with saccharine or Equal since "these have no affect on study analytes." (Protocol p. 4-32). It is relatively clear that sugar substitutes such as those used in diet sodas do not have a significant impact on thyroid function. However, the evidence for a lack of effect with caffeine is less clear. Studies in rats have shown that injection of caffeine results in a decrease in serum TSH followed by a subsequent decrease in serum T3 and T4 (Spindel et al., 1980). However, no effect on thyroid parameters were found in men (TSH and T3) or Syrian hamsters (TSH, T4, and T3) (Spindel et al., 1984; Bartsch et al., 1996).

* Figure 2A illustrates the variability in the fasting times. Though no direct correlation between urinary iodine (and perchlorate) measures and fasting times is seen, it is unclear whether fasting time, exclusive of all of the other variables 30 inherent in this dataset, could have affected urinary concentrations in a well-controlled dataset.

[Figure 2A: Variability of Fasting Times from NHANES 2001-2002 - See PDF Docket ID EPA-HQ-OW-2008-0692-1855]

Comment: 3. The observed differences in perchlorate are that thyroid response between men and women are not explained, which could be due to another unexplained variable. Comparable differences have not been observed in previous studies of perchlorate exposure (e.g., Greer et al., 2002; Braverman et al., 2006; Crump et al., 2000). Missing database variables make it difficult to exclude other possible causes of the observed differences between men and women.

* Thyroid autoantibodies are not measured in NHANES 2001-2002. Women are known to be about 2.7 times more likely to acquire an autoimmune disease than men (Jacobson et al., 1997), and to have a greater incidence of thyroid autoimmunity (Chiovato et al., 1993). Thyroid autoantibody levels have been shown to be positively correlated with TSH levels in humans (Hollowell et al., 2002; O'Leary et al., 2006; Hoogendoorn et al.,2006). In analysis of data from NHANES III, a significant association between female gender and elevated serum TSH levels disappeared when controlled for TPOAb (Hollowell et al., 2002).

* The NHANES dataset does not include a variable directly characterizing time since last pregnancy; this value can be approximated based on reported "age at last live birth" and current age. Using this, about 7.5% of women not currently pregnant reported being pregnant within the previous 2 years. The possibility that postpartum thyroiditis afflicted some of these women cannot be excluded. Postpartum thyroiditis, a syndrome of transient or permanent thyroid dysfunction caused by autoimmune inflammation of the thyroid, occurs frequently in the first year after delivery, with a prevalence of about 5-7% (Muller et al., 2001). In about 25-30% of these women, the condition progresses to permanent hypothyroidism (Lazarus, 2005b).

* Figures 3A and 4A depict the variability in the NHANES data set and the nominal changes noted in thyroid hormones.

[Figure 3A: Variability of Perchlorate in NHANES Data Set - See PDF Docket ID EPA-HQ-OW-2008-0692-1855]

Comment: 4. Spot urine concentrations of nitrate and thiocyanate, two other inhibitors of iodide uptake into the thyroid, were highly variable among study subjects. Since perchlorate, nitrate, and thiocyanate all act through the same mechanism of action (iodide uptake inhibition (IUI) at the thyroid), evaluation of correlations between exposure to iodide uptake inhibitors and thyroid hormone or TSH concentrations should take into account combined exposures to all three anions.

* Perchlorate equivalent concentrations of nitrate, thiocyanate, and perchlorate in urine in the study population (calculated assuming that nitrate is 1/240 as potent and thiocyanate is 1/15 as potent as perchlorate; Tonacchera et al., 2004) ranged from 3.7 to 3329 ug/L. On average, for any given subject, perchlorate comprised about 1% of the total perchlorate equivalent concentration (geometric means are 2.8 and 270 ug/L for perchlorate and perchlorate equivalent concentration, respectively). One would expect to see thyroid effects of nitrate or thiocyanate before seeing perchlorate effects; however, Blount et al. (2006) report no reliable associations between urine levels of nitrate and thiocyanate and serum total T4 or TSH.

* No correlation between perchlorate equivalent concentration and serum total T4 or serum TSH is apparent. Perchlorate equivalent concentration was not a significant predictor of total T4 (p=0.43, coefficient -0.00011) or TSH (p=0.25, coefficient -0.00023). Conceivably, the same problems inherent in relying upon spot urine samples as indicators of longer term iodine intake would affect the reliability of spot urine samples for perchlorate, nitrate, and thiocyanate.

Comment: Missing Data

Some of the key data related to this study were not accessible in the time frame of this project. For instance, the analytical quality assurance/quality control data is available for review through the National Center for Health Statistics (NCHS), but NCHS requires reviewers to request an appointment and travel to their location to review the data. Other data would need to be obtained under the Freedom of Information Act (FOIA). Key data that could be obtained through these mechanisms might include exact times of blood samples and urine samples, the sequence of sample collection, QA/QC of the analyses, analytical logbooks, and other notes from the survey. These are critical pieces of information that could be useful to characterize the dataset and examine the significance of associations.

Response: No response is needed for the information provided by the commenter.

Comment: Summary

If one considered this as a pilot study which would be consistent with the stated intended use, then the appropriate and logical next step would be to address a number of these concerns with an enhanced experimental design. For example, adding critical thyroid function variables (e.g., free T4, anti-TPO), 24-hour urine collections, and better control of medications will provide a more appropriate study design.

Re: Docket ID No. EPA-HQ-OW-2009-0297

Comments on Scientific Literature on Public Health levels of concern of perchlorate in drinking water

EPA is considering whether to specifically regulate the level of perchlorate in drinking water and needs to consider the potential adverse effect on human health, the frequency and level of exposure, and whether regulation of the contaminant represents a meaningful opportunity for reducing public health risks. EPA states that it is particularly concerned about the fetus of the iodine-deficient pregnant mother, infants, and developing children."

I review below the literature on the question as to whether the Blount et al. (2006) analysis demonstrates a risk from background perchlorate exposures on "the fetus of the iodine-deficient pregnant mother, infants, and developing children?" I conclude that it does not.

Lamm et al. (2007, under review) demonstrate that the primary Blount finding on perchlorate effect on thyroxine level at low iodine level is dependent on the definition of low iodine as low urinary iodine (<100UG/l) on a single sample. It is not found when creatinine-adjusted urinary iodine level is used as the metric for defining low iodine. Thus, the primary finding is dependent on analytic method and not robust to reasonable variants of definition.

Pearce et al.(2007, 2008 under review) demonstrate that maternal thyroid function is not adversely affected by background levels of perchlorate among first trimester pregnant women from mild or moderate iodine deficient populations or with low urine iodine levels (< 100 ug/L).

Review of published literature is consistent with findings of studies pending publication. Replication of the Blount et al. (2006) type analysis will be possible with the NHANES 2007-2008 dataset.

Regulatory assessment should not be considered independent of these findings. My presentations below provide the bases for the above statements.

Two major issues that I do not deal with here but that must be recognized is (1) that the biological effect proposed by the Blount et al. (2006) analysis is at an exposure level one to two orders of magnitude below that at which effects of perchlorate exposure have been observed and (2) that the issue of iodine adequacy for pregnant women and their offspring in the United states is important, complex, and appropriate for discussion elsewhere.

Is there a negative association between perchlorate and thyroxine with low iodine status?

Blount et al. (2006) is the only report that suggests that there is a biological effect from perchlorate at general US population exposure levels. They have analyzed data from NHANES 2001-2002 and report that women with low urine iodine levels have reduced total thyroxine (tT4) levels associated with increasing levels of urinary perchlorate, i.e., a negative association between urine perchlorate level and serum total thyroxine level among women with urinary iodine level < 100 ug/L. Steinmaus et al. (2007) further indicates that this finding is confounded by smoking.

The Blount et al. (2006) analysis has been interpreted as indicating that the children of women with low iodine status may be at increased risk of neurodevelopment deficit associated with their perchlorate exposure. This is an over-interpretation.

(1) There is no accepted measure for iodine status of an individual within a population. The reference point of 100 ug/L (or 100 ug/g creatinine) refers a population, not an individual. A low urine iodine level in a single urine sample does not equate to a finding of low iodine status.

The usual measure of iodine status is 24-h urinary iodine excretion, and the NHANES datasets do not give that metric. Historically, the 24-h urinary iodine excretion for an individual has been estimated from the urine iodine to urine creatinine ratio (e.g., Rasmussen 1999). This metric could be calculated from the NHANES dataset but is not included in the Blount et al. (2006) analysis. Even that would be a point estimate and not represent the general iodine status of the individual but only the iodine throughput status of that day. Andersen et al. (2001) have shown that single low measurements of iodine level on one day do not demonstrate as an average a low iodine level over multiple specimens over a long period of time (one year).

Laurberg et al. (2007) should get particular attention as it deals with many of the issues confronting EPA on perchlorate and has been developed independent of any perchlorate issues. They succinctly summarize the Andersen et al. (2001) paper as demonstrating that "in a group of people, the distribution of average iodine concentrations in several samples from the same subjects is much narrower than the distribution of values from single spot samples from the same people." They observe that "Only the median or average can be used to classify iodine intake." They conclude that "the concentration of iodine in a spot or casual urine sample cannot be used to diagnose iodine deficiency in an individual."

(2) The Blount et al. (2006) analysis has not analyzed separately these relationships for women of child-bearing age (WCBA, ages 15-44), which would be the relevant population with respect to protecting fetal health.

An analysis of the NHANES 2001-2002 data set for women of child-bearing age using iodine/creatinine as the metric of iodine exposure has examine the relationship of total thyroxine (tT4) with regarding to an association with urinary levels of perchlorate (and the other two iodine-uptake inhibitors, thiocyanate and nitrate) for those with low, medium, and high iodine/creatinine (Lamm et al., 2007). Lamm et al. (2007) has been published in abstract form and is currently under review for peerreview publication.

Lamm et al. (2007) demonstrated that "the negative association of serum thyroxine and urinary perchlorate found for WCBA with low iodine defined by UI (ug I/L urine) was not found for those

with low iodine defined by UICr (ug I/g creatinine)." Their analyses, in contrast, found such an association for WCBA with high iodine/creatinine.

This is not the place to discuss which of these two analyses are "right", but rather to observe that the Blount finding was highly dependent upon the specific metric used to classify low iodine. The lack of robustness with respect to the definition of low iodine suggests that the analytic results are method dependent, rather than a reflection of underlying biology. In this case, it is premature to serve as a basis for regulatory decision-making.

It should be noted that the Lamm et al. (2007 and 2010 pending) analysis of the NHANES 2001-2002 data set demonstrated that a negative association between serum thyroxine level and urinary thiocyanate level was found in WCBA with high iodine level rather than low iodine level, a finding consistent with a similar analysis of the NHANES III dataset (Vanderver et al., 2007). The replication of this finding in a second NHANES dataset is noteworthy. The Vanderver et al (2007) study further uses as its endpoint metric not the serum thyroxine level but the prevalence of hypothyroxinemia, which may be a better metric of outcome.

While the NHANES III dataset did not contain measurements of perchlorate, the NHANES 2007-2008 dataset that is currently being released does. The NHANES 2007-2008 dataset will be appropriate for examining these analytic issues. Analyses of the NHANES 2001-2002 dataset does not resolve them.

Comment: 2). A related, but different issue involves the use of spot urine testing to diagnose individuals as "low iodine intake" or "iodine deficient". I raise this concern for three reasons:

1). The Blount et al. and Steinmaus et al. analyses found significant effects principally in women with spot urine iodine levels <100 ug/L, not in those with spot iodine levels >=100 pg/L. However that 100 ug/L cut-off level is derived from a WHO/UNICEF/ICIDD criterion for determining iodine sufficiency in populations, not individuals.

2). There is a general consensus that "impacts of perchlorate exposure will vary depending upon an individual's iodine sufficiency" (15). Thus, predicting the adverse effects of perchlorate exposure requires knowledge of individuals' iodine sufficiency.

Response: EPA regulatory values and risk assessments are developed to protect the public health at a population level, acknowledging variability in the population as a source of uncertainty. Developing a health protective drinking water health advisory level that protects for potential adverse effects of sensitive subpopulations is EPA's approach to achieving this goal.

Comment: Moreover, a 1 ppb or lower MCL is supported by the most recent comprehensive studies, and these should be central to EPA's analysis. The industry-supported Greer study, which serves as the basis for EPA's current reference dose as well as California's current 6 ppb standard, consisted of a 14-day study of 37 healthy adults. In more recent years, Blount et al analyzed a nationally representative sample of 2299 U.S. residents, and they have documented anti- thyroid effects in a large population of women exposed to perchlorate at concentrations far lower than levels previously shown to have such effects. This study and subsequent data clearly justify promulgation of an even more protective MCL. It should be noted that California's Office of Environmental Health Hazard Assessment is in the process of reevaluating its Public Health Goal, on which the state MCL is based.

Response: EPA intends to determine the value for the MCLG in developing a proposed NPDWR with consideration of the best available, peer reviewed science. A value for the MCLG has not yet been determined.

Comment: Of great concern to us is the fact that women with low iodine status appear to be at particular risk of perchlorate effects. The study of Blount et al. demonstrated that among the 36% of women with urinary iodine values <100 ug/L in the NHANES 2001-2002 data set, there was a significant positive correlation between urinary perchlorate concentrations and serum TSH ($p=0.001$) and an inverse correlation between urinary perchlorate concentrations and serum T4 values ($p<0.0001$).12 Among women with urinary iodine values >100 μg/L, there was a positive association between urinary perchlorate concentrations and serum TSH ($p=0.025$), but there was no association between urinary perchlorate concentrations and serum T4 values. There were no significant associations between urinary perchlorate concentrations and thyroid function values in men irrespective of iodine intake. Therefore, if the results of this study are correct, the population at highest risk for adverse effects of environmental perchlorate exposure is women with low dietary iodine intake.

Response: EPA agrees that promoting iodide nutrition is good public health policy and may have a positive influence in reducing the iodide uptake inhibition effects associated with exposure to perchlorate. However, the Agency does not think it is appropriate to rely on the promotion of iodide nutrition in this case, especially since these activities are outside of EPA's SDWA authority. While the health concerns associated with perchlorate may be addressed through other means, it is the Administrator's judgment that a standard limiting perchlorate in drinking water can reduce health risk, particularly to fetuses, infants and children.

Comment: 4) THE USE OF THE NHANES DATA AS A POINT OF DEPARTURE

The NHANES 2001-2002 epidemiological urinary data are from a single un-timed spot urinalysis and can vary due to dilution or concentration of the urine (i.e., due to an individual's hydration status). A common technique to eliminate this variation in the spot urinalysis is to normalize the iodide urine concentration against creatinine resulting in the analysis expressing iodide excretion as ug of iodide/g of creatinine (i.e., ug/g creatinine) instead of ug of iodide/L of urine. Lamm has successfully repeated Blount's statistical analysis of the NHANES 2001-2002 epidemiological data only when his analysis measures UIC as ug/L (Lamm 2007). However, when Lamm 2007 repeats the statistical analysis using only women of childbearing age (ages 15-44 years) and UIC measured as ug/g creatinine, the statistical significance of the relationship between decreasing tT4 with increasing perchlorate exposure in women with low UIC is lost. The statistical significance of this relationship should be present regardless if the analysis expresses UIC in ug/L or ug/g of creatinine. This inconsistency suggests that the relationship between tT4 and perchlorate reported in the Blount analysis might be an artifact in the NHANES data set. The figures below show significant scatter in the perchlorate vs T4 and TSH correlations from the NHANES datset and cast considerable doubt on the clinical significance of any statistical significant findings reported by Blount et al 2006.

[Figure. Gender groups - Perchlorate vs T4 - see PDF docket ID EPA-HQ- OW-2009-0297-0636]

Additionally, studies among pregnant women do not demonstrate a correlation between urine perchlorate and thyroid function, A cohort of 789 pregnant women (i.e., 396 from Cardiff, Wales; 311 from Turin, Italy; and 82 from Dublin, Ireland) with perchlorate exposure levels shows no association between urinary perchlorate levels and free T4 levels in the pregnant women as a group or in the subgroup of pregnant women with UIC <= 100 ug/L (Pearce 2007). . A cohort of 230 pregnant women (i.e., 128 from Los Angeles, California; 102 from Cordoba, Argentina) with low perchlorate exposure levels predicted by the Blount analysis to induce a reduction of tT4 shows no association between urinary perchlorate levels and free T4 levels in the pregnant women as a group or in the subgroup of pregnant women with UIC <= 100 ug/L (Pearce 2008). From the 2005 Tellez cohort study (Tellez 2005) in three Chilean cities, a reanalysis of the data identified 16 of the pregnant women had UIC <= 100 ug/L (Gibbs 2008). The reanalysis shows no association between urinary perchlorate levels and free T4 levels in this subset of pregnant women with UIC <= 100 ug/L.

Comment: The Blount et. al. studies were useful in demonstrating that although perchlorate exposure is widespread (through diet), the review of the NHANES data clearly indicated that thyroid hormone levels measured in the study were clinically normal, even in the presence of perchlorate and other goitrogens such as nitrate and thiocyanate. The Blount et. al. 2006 study did show, however, that iodine nutrition is a significant concern, especially for women of childbearing age. The conclusions concerning associations purported in Blount et. al. 2006 are problematic as the authors failed to use consistent models to derive their findings across age, sex, ethnic and other key variables. Furthermore, it is hard to lend credence to associations between thyroid hormones and perchlorate exposure that are negative in one case for women with low urinary iodine excretion while being positive for other women. As a continuous variable, one might expect to see a more or less negative value between the groups, but not a complete change in the direction of the slope for a well-defined biological process. The statistical significance reported by the authors may be a result of the iodine level instead of the perchlorate level, as low iodine would result in elevated TSH and reduced T4 levels, while higher (i.e. sufficient) iodine levels would not be expected to result in a statistical association between thyroid hormone levels and iodine or perchlorate, as demonstrated in the study.

EPA Comment Code: 2200

Comment: Perchlorate has been found in the drinking water supply of 35 states and the District of Columbia. Widespread human exposure to perchlorate was confirmed by the Center for Disease Control's NHANES study, which found that 100 percent of the 2,820 randomly selected study participants had detectable levels of perchlorate in their urine. And according to your request for comment notice, dated August 5, 2009, the number of people served by water contaminated with high levels of perchlorate ranges between 53.4 and 16.8 million people.

Response: Under the first Unregulated Contaminant Monitoring Rule (UCMR 1). EPA collected and analyzed drinking water occurrence data for perchlorate from 3,865 PWSs between 2001 and 2005 under the UCMR 1. The minimum reporting level (MRL) for perchlorate under the UCMR 1 was 4 µg/L. EPA found that 160 (approximately 4.1 percent) of the 3,865 PWSs that sampled and reported had at least 1 analytical detection of perchlorate (in at least 1 sampling point) at levels greater than or equal to the MRL of 4 µg/L. These 160 PWSs are located in 26 States and 2 territories. Of these 160 PWSs, 8 are systems serving 10,000 or fewer people and 152 are systems serving more than 10,000 people. These 160 systems reported 637 detections of perchlorate at levels greater than or equal to 4 µg/L, which is approximately 11.3 percent of the 5,629 samples collected by these 160 PWSs and approximately 1.9 percent of the 34,331 samples collected by all 3,865 PWSs. The average concentration of perchlorate for those samples with positive detections for perchlorate was 9.85 µg/L and the median concentration was 6.40 µg/L.

Table 1 in the final regulatory determination presents the number and percentage of PWSs that reported perchlorate at levels exceeding various threshold concentrations.

Table 2 of today's notice presents EPA's estimates of the population served by PWSs that were monitored under UCMR 1 for which the highest reported perchlorate concentration was greater than the thresholds identified in Table 1. These population estimates are for people at all life stages. EPA has determined that a NPDWR for perchlorate could reduce perchlorate exposures for these populations to levels below the potential alternative HRLs that EPA has identified as levels of public health concerns for purposes of this determination, and that such exposure reductions present a meaningful opportunity for the reduction of health risks for persons served by PWSs.

Comment: U.S. EPA uses the US Centers for Disease Control and Prevention's National Health and Nutrition Examination Survey (NHANES) biomonitoring dataset in concert with the FDA TDS dataset to estimate the relative proportional intake of perchlorate from both food and water sources. The NHANES data provide the best available measure of actual human exposure to perchlorate from all sources, including food and water, using urinary perchlorate concentrations from a large U.S. population cohort. The overall exposure to perchlorate from all sources based on the NHANES data is below any meaningful level of concern identified in the available scientific literature. Thus, as a fraction of total exposure, intake of perchlorate from food alone must be well below any meaningful level of concern. FDA's TDS and food sampling data, which provides an approximation of human exposure to perchlorate from food, validates this conclusion.

Recent Epidemiological Data, Including the Blount (2006) Analysis of NHANES Data, Should Not Be Used as a Basis for a New Perchlorate Regulatory Determination.

The undersigned groups support EPA's decision to base its perchlorate regulatory determination on the NAS RfD. Some have argued that the Blount (2006b) results, which show a slight correlation between perchlorate in urine and changes in thyroid hormone levels in women with sub-optimal iodine levels, should be given considerable weight in EPA's review of its preliminary regulatory determination. In fact, the Blount analysis has several limitations which necessarily impede its use in drawing conclusions regarding the health effects of perchlorate, particularly for purposes of risk assessment and regulatory decision making. Chief among these is the fact that Blount (2006b) does not establish direct causation, only an association between two independent data sets. A number of intervening factors could cause or contribute to the reported decrease in thyroid hormone levels, including methodological issues such as the use of relevant measures of thyroid function (total T4 versus free T4) and appropriate biomonitoring data (24 hour urine versus spot urine samples). Second, even if changes in thyroid hormone levels were considered adverse (they are not), the changes identified in Blount (2006b) were not outside the normal ranges for thyroid hormone levels. Third, estimated perchlorate doses based on the urinary concentrations were below the level that can

trigger inhibition of iodide uptake, the non-adverse precursor effect that is the basis of the NAS NOEL.

The Blount (2006b) results conflict with the overwhelming body of scientific evidence showing that perchlorate has no effect on the thyroid at environmentally relevant levels. Similar concerns have been raised by independent organizations such as the American Thyroid Association[FN2: The American Thyroid Association in 2007 concluded that the CDC study findings were "intriguing," but limited in their application to the setting of exposure standards. (http://www.thyroid.org/professionals/publications/statements/06_12_13_ perchlorate.html).], and a key member of the NAS perchlorate panel has indicated that the NAS RfD remains sufficiently health protective[FN3: In April 2007 - after publication of the CDC study - NAS panelist Dr. Robert Utiger, senior physician with the Harvard Institutes of Medicine, testified before Congress and stated: "I continue to believe that a reference dose of 0.007 mg/kg/day (24.5 ppb) is quite adequate."].

Response: EPA disagrees that the overwhelming body of scientific evidence showing that perchlorate has no effect on the thyroid at environmentally relevant levels. See response to comment ID 29078 under comment code 2200.

Comment: If the association between perchlorate and thyroid hormone levels was causal, as is sometimes inferred from the Blount study, then logically the effects of thiocyanate and nitrate observed by Blount in connection with those same hormones should also be viewed as causal. If that were so, it would then appear that thiocyanate has all of a sudden become a remedy against goitrogens instead of a goitrogen itself, and nitrate would only act as a goitrogen when iodine levels were sufficient. That of course would be very surprising, and would be inconsistent with years of scientific observations and studies regarding these substances. As discussed in greater detail below, we have reviewed the information presented in the Blount study regarding perchlorate, and the full range of substances in the same NHANES 2001-2002 database, and have concluded that perchlorate is not the cause of observed TH impacts, but is simply a marker for other thyroid affecting substances.

1. The four orders of magnitude difference between the adverse effect levels found in the two most cited recent studies in relation to perchlorate, the Greer study and the Blount study

In stark contrast to all previous studies, the results of the Blount study suggest that if the relationship between perchlorate and thyroid hormones is causal, perchlorate is about 10,000 times more potent than previously found. It is simply not plausible that all other studies would have missed this surprising outcome, particularly in view of the fact that perchlorate was and still is used as a drug in the treatment of thyroid disorders.

From Blount (NHANES 2001-2002) data and regression curves, the average urinary level of 2.84 ug/L, which is found to be related to thyroid hormone (TH) change, is equivalent to an oral perchlorate dose of approximately 0.00004mg/kg- day[FN2: Blount BC, Valentin-Blasini L, Osterloh JD, Mauldin JP, Pirkle JL, 2006a. Perchlorate Exposure of the U.S. Population, 2001-2002. Journal of Exposure Science and Environmental Epidemiology, 1-8.]. This is 100 times lower than the dose of 0.004 mg/kg-day that was found in the Greer study to be without effect not even on iodide uptake and which led to the NAS RfD based on a (slightly higher) NOEL of 0.007 mg/kg-day. Further this dose of 0.004 mg/kg-day on itself is about 100 times smaller than 0.5mg/kg-day, the dose found to have no effect on THs[FN3: NAS 2005, Health Implications of Perchlorate Ingestion, The National Academies Press, Washington, DC, 2005.]. So, in stark contrast to what has been found in the body of the literature, the conclusions of the Blount study would suggest that perchlorate is about 10,000 times more potent than measured in previous studies as illustrated in fig. 3, below.

Fig. 3 [see PDF docket ID EPA-HQ-OW-2009-0297-0647]

The NAS RfD of 0.0007 mg/l has often been expressed in the media as "a couple of drops in an Olympic seized swimming pool" to make it more visually comprehensible. We could push this metaphor a bit further: the 10,000 times lower dose would then mean that the level represents a couple drops in 10,000 Olympic sized swimming pools. If the effect of perchlorate were indeed so strong, the resulting drinking water public health goal (PHG) would be well below 25/100 ppb and closer to 25/10,000 ppb or 0.0025 ppb which is at least 2 orders of magnitude below the mean natural perchlorate background in drinking water.

Finally, if the causal interpretation of the results of the Blount study are to be believed, the downstream TH adverse effect level of 0.00004 mg/kg-day would be 2 orders of magnitude lower than the upstream iodine uptake inhibition non- effect level. This is in itself contradictory, since according to NAS "a perchlorate dose that does not inhibit thyroid iodide uptake will not affect thyroid function" (ref. 2 above) and thus cannot affect TH levels.

A sudden four order of magnitude difference in effect level attributed to a well studied substance is extremely improbable. It is instead far more likely that the study's interpretations regarding the impact of low doses of perchlorate are inaccurate and should not be relied upon as a basis for regulation.

2. The cause of the TH changes in the Blount et al. study: is it another substance or an environmental pool of substances?

Comment: B. Recent Studies Listed in the 2009 FR Notice

The Notice states that EPA has evaluated additional data made available since the 2005 RfD determination. In response to comments suggesting that other studies, particularly Blount et al. (2006), be used for defining a regulatory standard, EPA noted that new studies have provided important information to the scientific literature, but that it has "decided to make the regulatory determination based upon the current RfD." The papers EPA listed are summarized below. Based on these data, Greer et al. (2002) continues to provide the best scientific information to be used as the basis for EPA's perchlorate RfD risk assessment.

Most of these comments have been presented by Intertox in the past. Where appropriate, however, these summaries are updated with new information.

Blount et al. (2006)

Using the NHANES 2001-2002 data set and a cross-sectional study design, Blount et al. (2006) report measurement of urinary perchlorate, urinary iodide, serum TSH, and serum total T4 levels in men and women over the age of 12. The 2001-2002 NHANES data provide the largest group of subjects to date from which sampling data can be derived. The authors report that perchlorate levels were not associated with total T4 or TSH levels in men, but were a negative predictor of total T4 and a positive predictor of TSH in women with urinary iodine less than 100 ug/L. They report that in women with urinary iodine greater than 100 ug/L, urinary perchlorate was a positive predictor of TSH, but not associated with T4. The significance of evaluating women with urinary iodide less than 100 ug/L is based on the World Health Organization (WHO) statement that a median urinary iodine concentration for the entire population, based on spot samples of less than 100 ug/L, is indicative of overall iodine deficiency for that population (WHO, 2004).

This study has drawn a great deal of attention as it may be misinterpreted to demonstrate an "effect" of perchlorate, albeit at exposures below those that cause measurable IUI. A number of considerations, however, should be noted to better understand the significance of the data reported.

First, as stated above, ATSDR (2008) reviewed this study in their assessment and did not feel it merited any special consideration over other studies in the well developed perchlorate literature database. It states that its decision "...was made after a careful evaluation of the NRC report and of studies that have been published after the NRC (2005) report. The results from newer studies do not change the bottom-line recommendation" (ATSDR, 2008).

Second, it is important to interpret the results of scientific research based on what is known about the biological system. For example, there is a difference between "statistical significance and "clinical significance." A "statistically significant" difference simply means it is unlikely that a difference between two variables (e.g., measurements) is due to chance. With a well designed experiment, statistical significance can be extremely important. Because statistical significance is also a function of sample size, variability in the variables measured, etc., the finding of statistical significance does not necessarily mean the difference is large, important, or biologically significant. For biological data, it is important to understand whether something that is statistically significant is also clinically significant; that is, whether a change in a variable or parameter is large enough to affect a clinical or medical condition (e.g., development of hypothyroidism). Blount et al. (2006) report statistically significant relationships for some variables, but do not report any variables with clinical significance, such as free T4.

The type of study conducted by Blount and colleagues (i.e., a cross-sectional study) cannot determine causation, only association between the variables studied (Wartenberg and Buckler, 2001). If important variables are missing, then spurious conclusions can be made. Thus, without a full set of thyroid-specific variables measured, including repeated 24-hour urinary iodide measurement, any association should be examined carefully for reliability.

Furthermore, perchlorate did not actually lower (nor was it associated with) thyroid hormone levels outside the normal range of values. Assuming that it had, the NRC committee does not think that "...transient changes in serum thyroid hormones or TSH concentrations are adverse health effects; they are simply biochemical changes that might precede adverse effects" (NRC, 2005). For each individual in the NHANES study, a single spot urine sample and a single plasma sample for analysis of thyroid hormones and other parameters were collected. These data do not provide more than a "snapshot" or transient assessment of these individuals.

Regarding Blount et al. (2006), ATSDR states, "limitations of the study acknowledged by the investigators include those common to cross-sectional analyses, the assumption that urinary perchlorate correlate with levels in the thyroid stroma and tissue, and the measurement of total T4 rather than free T4" (ATSDR, 2008).

Third, any study must have careful consideration for the parameters and variables that are measured or available and how these variables relate to the outcome of interest. NHANES is designed to collect a broad range of data about the health and diet of people in the United States. NHANES collected data on some parameters relevant to thyroid function, but these parameters fall short of providing sufficient information needed to clearly understand thyroid health. Only two clinical measures of thyroid function were taken (total serum T4 and TSH). Missing where free T4, thyroid binding globulin (TBG), and T3 among others. Iodine status was reported on the basis of spot urine samples, which are neither the preferred, nor most reliable, measure of urinary iodide (Barr et al., 2005). Further, NHANES did not collect data on the incidence of autoimmune thyroiditis, the most common thyroid disorder in the U.S., which causes changes in serum T4, T3, and TSH concentrations due to errant immune mechanisms attacking the thyroid gland, called Hashimoto's thyroiditis (NRC, 2005). Intertox (2008) provides a more thorough discussion regarding the use of spot urine testing, confounders, and use of the available NHANES variables to draw conclusions.

This study did not present urinary measures normalized to creatinine, although creatinine was included as a variable in the regression analysis. The concentration of dissolved substances in urine, such as iodide, may vary between individuals or between samples from the same individual based on water intake. Normalization with creatinine is meant to normalize for dilution, not variability due to differences in exposure. It is not a perfect method, but is commonly used to account for this dilution (Furnee et al., 1994). Normalization may have been particularly useful in dividing the women up in to those with urinary iodide less than and greater than 100 ug/L.

EPA Comment ID: 28899

EPA Comment Code: 2200

Comment: Fourth, not only were the thyroid hormone values within normal clinical ranges, but urinary perchlorate levels as a surrogate for dose demonstrate that these perchlorate exposures are well below the threshold for zero inhibition of iodide uptake, a nonadverse effect. Exposures that are below the threshold for iodine uptake inhibition are below the NOEL for perchlorate and are not adverse (NRC, 2005; Greer et al., 2002).

Finally, based on the premise that science is incremental and knowledge builds collectively over time, concerns raised by scientists related to the Blount et al. (2006) study should be considered an opportunity for further study. Furthermore, recognizing that urinary spot iodine or single point iodine measures are not a good indicator of iodine status, a different approach is being considered by Dr. Blount. More research should be conducted to better understand the results of this study.

EPA Comment ID: 29078
EPA Comment Code: 2200

Comment: The key findings of the Blount study are well known:

1) Measures of thyroid function (T4 and TSH) were significantly associated with urinary perchlorate levels in women, but not men;

2) T4 levels were negatively associated with urinary perchlorate levels in women with spot urine iodine levels <100 ug/L, but not >=100 ug/L. TSH levels were positively associated with perchlorate in both groups of women;

3) Urinary thiocyanate levels were negatively associated with TSH in women with spot urine iodine levels >=100 ug/L, but there was no association in those with <100 ug/L. Urinary thiocyanate levels were not significantly associated with T4 in women with spot urine iodine levels <100 ug/L or >=100 ug/L;

4) Urinary nitrate levels were negatively associated with T4 in women with spot urine iodine levels >=100 ug/L, but not in those with levels <100 ug/L. Urinary nitrate levels were not significantly associated with TSH in women with spot urine iodine levels <100 ug/L or >=100 ug/L.

The Blount perchlorate findings are provocative, and at first seem biologically plausible. But when all study findings are viewed together, their pattern is inconsistent with what is generally accepted to be the basic physiology of the Sodium/Iodide Symporter (NIS).

Three principal anions, perchlorate, thiocyanate and nitrate (along with other 'lesser' anions) exert qualitatively similar effects upon the thyroid, i.e., they competitively inhibit iodine uptake by the NIS (2-5). The NIS effects of these molecules have been shown repeatedly to be similar in direction and

additive in magnitude, and their quantitative relationships have been well characterized (6-12). Accordingly, it is reasonable to expect that the effects on iodine uptake of increasing exposure to perchlorate, thiocyanate and nitrate would be directionally similar and quantitatively predictable.

That viewpoint is widely held by EPA scientists and others. Consider, for example, the views expressed in the recent report of the EPA's Office of Inspector General (OIG) (13):

"... the human body is exposed to all three NIS inhibitors concurrently and the resulting effect on the uptake of iodide by the thyroid is cumulative and indistinguishable from each other ..."

"The three NIS inhibitors (thiocyanate, nitrate, and perchlorate) exceed EPA's 'mode of action' requirement by sharing the same 'mechanism of toxicity' (i.e., simple competitive interaction) by inhibiting the uptake of iodide at the NIS..."

Likewise, Blount et al. agree that thiocyanate, nitrate, and perchlorate share activity as competitive inhibitors of iodine uptake (1):

"the ability of NIS to transport adequate amounts of iodide depends on the relative concentrations of these competing anions".

Steinmaus et al. also concur (14):

"High doses of perchlorate have been shown to competitively inhibit iodide uptake in the thyroid gland ... other agents, including nitrate in food and water and thiocyanate in food or from tobacco smoke also affect the thyroid by the same mechanism."

De Groef et al., in consideration of expected half-lives and exposure levels of these anions, concluded that the anti-thyroid effect of perchlorate was similar to, but substantially smaller than the respective effects of thiocyanate and nitrate (12):

"perchlorate accounts for less than 10% of possible thyroidal effects resulting from the exposure from drinking water; in food, its share is even negligible."

The inconsistencies in the Blount data are shown in the following table, which indicates the direction of expected effects on T4 and TSH levels resulting from increased exposure to perchlorate, thiocyanate or nitrate, and the effects on T4 and TSH levels observed in various groups as reported by Blount et al. No consistent pattern of effects is seen, and observed effects are not all consistent with expected.

Expected Effects and Reported Significant Effects on T4 and TSH from Increasing Exposure to Perchlorate, Thiocyanate and Nitrate [see table in PDF docket ID EPA-HQ-OW-2009-0297-0209]

Also surprising is the general absence of effects attributable to thiocyanate and nitrate. As emphasized in the OIG analysis, "typical human exposures" to thiocyanate and nitrate should have induced "substantially more NIS inhibition" than that caused by 13 ug/day perchlorate exposure, the 95th percentile exposure level in the Blount study (13).

Blount et al. recognized that such results were surprising:

"unexpected based on a mechanism of NIS inhibition. The explanation for this is unclear"(1).

Although various hypothetical and speculative explanations were proposed for such apparent inconsistency, I am not aware that any has actually been validated.

Steinmaus et al., in their re-analysis of the NHANES and Blount data, evaluated the impact of urinary thiocyanate levels on the associations between urinary perchlorate and thyroid function noted by Blount et al. (14). Like Blount, they found no significant effects in males and no significant effects in women with urinary iodine levels >=100 ug/L. And also like Blount, they recognized and could not explain the inconsistencies of their results. They could not explain the observed gender-specificity:

"We do not know why the effects we identified were seen only in women".

Similarly, they could not explain the absence of effects for nitrate, which "requires investigation beyond the scope of this paper". Finally, they could not explain the absence of perchlorate- and thiocyanate-related effects in women with spot urine iodine levels >=100 ug/L.

It is not known whether the inconsistent results reported in Blount and Steinmaus reflect yet-to-be-elucidated physiological relationships, heretofore unrecognized sources of confounding, or just 'bad luck' that adversely impacted the composition of the study cohort. Whichever, it is apparent that these data are not adequate to serve as the basis for regulatory rule making. There are too many inexplicable scientific uncertainties that can only be addressed by hypothetical and speculative thinking. Moreover, it is unlikely that reanalysis of the 2001-2002 NHANES data and Blount analyses can resolve these concerns, nor can the Steinmaus et al. analysis be used to validate the Blount et al study, as emphasized in the OIG report (13):

"the Steinmaus analysis does not corroborate the Blount analysis because both studies use the same NHANES 2001-2002 data set."

In summary, the Blount et al. and Steinmaus et al. studies are provocative and useful as the bases for hypothesis generating. They are not, however, adequate for hypothesis testing and their conclusions remain too speculative and uncertain to provide a sound basis for regulation.

Response: EPA has evaluated the Blount and Steinmaus papers as well as the OIG report cited by the commenter. EPA has determined that these studies and report are informative, but the Agency believes the recommendations of the NRC represent the best available peer reviewed science on which to base a regulatory determination. EPA believes the NRC appropriately based the RfD on iodide uptake inhibition to the thyroid, for the reasons discussed in its report. See further discussion of the RfD in today's Federal Register notice. With respect to effects of nitrate and thiocyanate, data do not exist at this time to permit a quantitative assessment of potential cumulative effects of perchlorate and other compounds that impact the sodium iodide symporter. However, EPA has committed to a drinking water strategy that outlines four principles to expand public health protection for drinking water (USEPA, 2010b). One of these principles is to address contaminants as groups. However, EPA does not believe that regulatory action to address perchlorate should be further delayed. Therefore, EPA intends to develop a proposed rule for perchlorate. EPA will continue to analyze the best available science in developing the proposed rule.

EPA Comment Code: 2300 Use of PBPK models from Clewell et al (2007) and Merrill et al (2005) to evaluate health effects

Response to Comment Code 2300: EPA reviewed, modified, and applied the perchlorate Physiologically-Based Pharmacokinetic (PBPK) models, which were originally developed by Merrill et al. (2005) for adults and Clewell et al. (2007) for other life stages, to estimate the iodide uptake inhibition in the thyroid for each life-stage (73 FR 60262; USEPA 2008a). Estimated ingestion rates were then used to estimate the internal dose and resulting iodide uptake inhibition for several life stages, including susceptible populations (e.g., pregnant women and their fetuses, as well as breast-fed and bottle-fed infants).

In the August 2009 notice, EPA stated that it was re-evaluating how best to incorporate the PBPK modeling analysis into its evaluation of perchlorate — if at all. The Agency sought comments on ways to use the PBPK modeling analysis to inform the regulatory determination.

Several commenters supported the use of the PBPK model to inform the regulatory determination only if the significant limitations of the current model are addressed. For example, the inability of the model to reflect iodide nutritional status was cited by commenters and three of four peer reviewers as an important limitation (USEPA, 2008d). Also, several commenters stated that the risks to breast-fed infants and young children are not adequately addressed by the model. They challenged that the modeling analysis is based on average weight infants and healthy adults, while the sensitive life stages for perchlorate include premature infants and hypothyroid women.

After further consideration of the peer review and public comments, EPA concludes that the PBPK modeling analysis, in the context of the perchlorate regulatory determination, is useful in examining which life stages are most susceptible to the effects of perchlorate. For example, the model indicates that a fetus may be seven times more sensitive to the effects of perchlorate than a pregnant woman. The model also allows for the estimation of the concentration of perchlorate in breast milk (thus breast-fed infant exposure) at various maternal perchlorate exposure levels. However, because of the stated limitations, EPA has decided the model does not directly bear on the current decision regarding the need for a NPDWR for perchlorate. EPA is continuing to evaluate whether the model could be used in setting a NPDWR for perchlorate.

EPA Comment ID: 20773
EPA Comment Code: 2300

Comment: This decision has been based in large part on an unvetted, industry funded computer model. Any studies of this kind are highly suspect and must be verified by proper scientific studies.

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination. This model has been extensively vetted, with publication of the

perchlorate specific model (Clewell et al. 2007) in a reputable journal. In addition, EPA has subjected the modified model to peer review and revised the model in accordance with peer reviewer recommendations.

Commenter Name: Anila Jacob
Commenter Organization: Environmental Working Group
EPA Document ID: EPA-HQ-OW-2008-0692-1432
EPA Comment ID: 20899
EPA Comment Code: 2300

Comment: Instead of using state of the art science and human bio-monitoring data from the Centers For Disease Control and Prevention (CDC) to assess risks, the agency employs a highly questionable, non-peer reviewed computer model developed by the discredited industry front group, the Chemical Industry Institute of Toxicology (CIIT). The choice to use a model instead of real world data was done for one reason, to make the risks from perchlorate look smaller than they really are. The model did achieve that result, but even this faulty analysis did not completely exonerate this potent thyroid toxin. In the end, this computer model predicts that 30,000 pregnant women would be exposed to perchlorate in drinking water at levels that exceed EPA's health reference level (HRL) of 15 ppb at any given time (EPA 2008).

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination. EPA acknowledges the Blount et al (CDC) analysis of effects of perchlorate on the thyroid status of women with low urinary iodide. However, the applicability of the analysis is limited by deficiencies noted by the authors. See response to comment code ID 28515 under comment code 2200.

Commenter Name: Anila Jacob

EPA Comment ID: 20904
EPA Comment Code: 2300

Comment: Other noteworthy errors and flaws in this assessment include the following:

* The physiologically-based PBPK model that EPA uses in their assessment was designed by researchers who work for the CIIT, an industry funded research organization with a history of providing assessments to EPA that favor industry interests;

* The PBPK model that EPA uses in their assessment relies heavily on the flawed, industry-funded Greer study;

* EPA essentially ignores data from large, well-conducted human studies in favor of a PBPK computer model;

Response:
See response to comment code 2300 for a discussion of PBPK modeling in and considerations in this regulatory determination. EPA acknowledges the Blount et al. analysis of effects of perchlorate

on the thyroid status of women with low urinary iodide. However, the applicability of the analysis is limited by deficiencies noted by the authors. See response to comment code 28515.
See also response to comment ID 20899 under comment code 2300.

Commenter Name: Anila Jacob
Commenter Organization: Environmental Working Group
EPA Document ID: EPA-HQ-OW-2008-0692-1432
EPA Comment ID: 20910
EPA Comment Code: 2300

Comment: EPA relies on PBPK model that was designed by industry-funded group: EPA relies heavily on the PBPK model in their assessment; this model was designed in part by scientists who work for the CIIT, which is an industry-funded organization that is sponsored by corporations such as 3M, BASF, Dow, and ExxonMobil and trade groups such as the American Chemistry Council and the American Petroleum Institute.

The CIIT has a history of conducting assessments that result in outcomes that favor industry. In a 2008 report, the Government Accountability Office (GAO) notes that the CIIT developed a risk assessment for formaldehyde that was 2,400 times less stringent than a previous Integrated Risk Information System (IRIS) estimate (GAO 2008). The GAO report goes on to note "The decision to use the CIIT assessment in the plywood national emissions standard was controversial, and officials in EPA's National Center for Environmental Assessment said the center identified numerous problems with the CIIT estimate" (GAO 2008).

In 2004 the CIIT also published a model for the contaminant trichloroethylene (TCE) that proposed cancer risk values for TCE inhalation that were 300 times less protective than EPA's 2001 proposed values (Clewell et al. 2004). Leading EPA researchers subsequently published a critique of the CIIT's work, stating that their literature review did not present a "sufficiently current, complete, accurate, and transparent review of the pertinent literature," and concluding that the resulting model had not been adequately described or validated (Caldwell et al. 2006). EPA scientists also noted that the CIIT had failed to disclose their funding for the TCE model, and inappropriately implied that it had been funded by EPA.

In addition, EPA itself has noted errors in the CIIT PBPK model used in the perchlorate assessment, explaining in their report, "EPA evaluated the PBPK model code provided by the model authors and found minor errors in mathematical equations and computer code, as well as some inconsistencies between model code files" (EPA 2008). It is unclear why EPA relies so heavily on the CIIT generated PBPK model when the CIIT has a history of conducting industry friendly assessments, as with the formaldehyde example, and there are clear errors in the perchlorate model, as acknowledged by EPA.

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination. As the commenter notes, EPA modified the model of Clewell et al. (2007) to correct minor mathematical errors and to expand the capabilities to reflect additional life stages. This work was conducted with the consent and support of the model developers. The model was previously peer reviewed and published in a reputable journal.

EPA does not believe that CIIT's work on formaldehyde or TCE is relevant to the perchlorate assessment.

EPA Comment Code: 2400 Use of EPA's PBPK model to evaluate health effects

Commenter Name: Melanie A. Marty, Ph.D.
Commenter Organization: Children's Health Protection Advisory Committee
EPA Document ID: EPA-HQ-OW-2008-0692-0962
EPA Comment ID: 20417
EPA Comment Code: 2400

Comment: The Agency justifies the high MRL [sic] by a pharmacokinetic model that simulates iodine uptake inhibition in the human fetus and newborn based upon experimental data in rat pups. While the model has been validated in adult humans and rat pups, it has not been validated in infants and children. As we described in the CHPAC 2006 letter, use of the rat data to project pharmacolcinetics to human newborns is uncertain given the well known differences in the rate of development of clearance mechanisms between rodents and humans. The modeling performed by the Agency does not remove the clear concern for elevated neonatal exposure to perchlorate, well in excess of the RfD. This also represents an unorthodox use of pharmacokinetic modeling in regulatory risk assessment because once an RfD is established, it is inappropriate to use additional modeling to justify exceeding the RfD.

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination.

Commenter Name: Carol Rowan West
Commenter Organization: Massachusetts Department of Environmental Protection
EPA Document ID: EPA-HQ-OW-2008-0692-1422
EPA Comment ID: 20433
EPA Comment Code: 2400

Comment: 4. The PBPK Model is Uncertain Especially for Iodine Insufficient Women. Instead of using the standard approach of comparing estimated doses to the RfD to determine safe drinking water levels, EPA is instead relying on physiologically-based pharmacokinetic (PBPK) modeling to predict IUI. MassDEP believes that the PBPK modeling has a number of limitations and may be less reliable. For example, the PBPK modeling does not adequately address effects in iodide insufficient populations and is very uncertain with respect to predicted breast milk perchlorate concentrations, effects on neonates and impacts during early fetal development. Empirical data on these issues is sparse, limiting model construction and evaluation. More robust uncertainty analysis and evaluation of model outputs is needed.

5. EPA Needs to Better Assess and Present PBPK Model Uncertainties. Since EPA relies heavily on the outputs of the PBPK model to predict breast milk perchlorate levels, a more thorough presentation of the model, model uncertainties and its outputs, in particular for breast milk perchlorate concentrations and neonatal exposures under differing maternal exposure scenarios is needed. This information should be provided to the public for review and comment, in addition to a

scientific peer review session. These are uncertain because the PBPK model relied on rat data for several key parameters that influence breast milk perchlorate concentrations. Furthermore, the model was only evaluated against limited human data derived from populations in Chile (Tellez et al., 2005).

6. US Data Indicates the PBPK Model May Underestimate Breast Milk Perchlorate. Due to differences in dietary iodide intake rates, which are likely to be much higher in Chile, as well as other factors, breast milk data from US populations with lower levels of iodine intake, such as from the Boston study (Pearce et al., 2007), should also be used for model evaluation. Based on the Pearce et al., study, MassDEP is concerned that the model may significantly underestimate perchlorate breast milk concentrations in US women. Table 1, compiled by MassDEP, compares observed perchlorate and iodide concentrations in breast milk and perchlorate in urine from the Chilean and Boston study populations. These data are consistent with higher dietary iodide intake levels in the Chilean populations compared to the Boston area. The US data also exhibits a higher breast milk to urine perchlorate concentration ratio compared to those observed in the Chilean study groups - a factor of 4 for the Boston data vs. a range of only 0.33 to 2 for the Chilean populations. This suggests that the Boston women, perhaps due to lower iodide intake, may have partitioned a greater fraction of perchlorate dose into breast milk than predicted by the model. This would result in even higher neonatal exposures than predicted by EPA at a maternal drinking water concentration of 15 ug/L, which as noted above, already exceeds the RfD.

[Table 1. Lactational Perchlorate and Iodide levels in Urine and Breast Milk - see PDF Docket ID EPA-HQ-OW-2008-0692-1422]

7. The PBPK Model is Deficient for Early Developmental Periods. Emerging data now indicate that thyroid hormone deficiency during early gestation causes neuronal toxicity (Sinah et al., 2008). The EPA has acknowledged that the lack of biological information during early fetal development limits the applicability of the PBPK modeling of the fetus and thus can not make meaningful predictions regarding early fetal IUI.

8. The PBPK Model Does Not Consider Other Potential Mechanisms of Toxicity. Additionally, the model only addresses iodide uptake inhibition. However, perchlorate not only inhibits iodide uptake but also promotes the discharge of endogenous iodide, which is not addressed in EPA's assessment. The thyroid gland possesses two kinds of iodide. The first is the iodide which is accumulated into the thyroid by an active transport mechanism, the so-called "transported iodide". The second source is the iodothyronins which are derived by hydrolysis from thyroglobulin and rapidly deiodinated within the gland to yield the so- called "endogenous iodide". It is believed that both iodide sources are used within the thyroid gland for the synthesis of hormones. Rosenberg et al., 1961; Isaacs et al., 1966; Greer et al., 1969 showed that perchlorate discharged endogenous iodide in animals, and Burgi et al.(1974) confirmed this phenomenon to occur in humans. Wolff (1974) has attempted to propose mechanisms by which perchlorate accomplishes the discharge of stored thyroidal iodide, but how this process affects thyrocytes upon short- and long-term exposure is not well understood and is not covered by the PKPB modeling.

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination.

Comment: Proposed HRL of 15 ug/L for Perchlorate

In 2006, USEPA adopted an IRIS Reference Dose (RfD) of 0.7 ug/kg/day for perchlorate, based on the advice of the National Research Council (NRC) Committee to Assess the Health Implications of Perchlorate Ingestion (2005), which had been assembled at the request of USEPA.

The proposed Health Reference Level (HRL) for perchlorate of 15 ug/L was derived using exposure assumptions for a pregnant woman/fetus exposed to the RfD of 0.7 ug/kg/day with a Relative Source Contribution (RSC) factor of 0.6. In developing this HRL, USEPA assumed that the fetus is the most sensitive subpopulation, more sensitive than the infant, so that the infant can be safely exposed to much higher doses than the fetus. After deriving the HRL of 15 ug/L based on exposure of the pregnant woman/fetus, a physiologically-based pharmacokinetic (PBPK) model was used to evaluate the dose reaching the thyroid and to estimate effects on the inhibition of thyroidal iodine uptake in sensitive subpopulations exposed to 15 ug/L of perchlorate.

Insufficient information has been provided to the public about the details of the PBPK model to allow for the necessary evaluation of this approach. The proposal states that USEPA modified the published PBPK model to reflect the decreased urinary clearance of young infants and for other reasons, but the citation for this information (USEPA, 2008b) does not provide a document that is available to the public. Additionally, USEPA states that the modifications it has made to the published model have not yet been peer reviewed, and that this peer review will take place prior to finalizing the proposal. We believe that the results of the peer review should be available as part of the USEPA proposal, so that the public can consider the conclusions of the peer review as to the appropriateness of the approach used by USEPA.

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination. The modifications to the Clewell (2007) model were peer reviewed and found to be sound. The peer review report can be found on EPA's website at http://water.epa.gov/drink/contaminants/unregulated/perchlorate.cfm. The major reservation expressed centers on attempting to use the model beyond its capabilities.

Comment: Another matter of concern is the assumption that a 2.2% decrease in iodide uptake in 7-day old infants can be regarded as a No Effect Level (73 Fed. Reg. 60278 (October 10, 2008)) by extrapolation from the NRC panel's conclusions. The NRC based the conclusion that a 1.8% decrease was a No Effect Level on data from normal healthy adults. Additionally, the 1.8% decrease was considered to be within the normal variation expected in an experimental measurement, which differs in concept from a prediction of a decrease of any magnitude by a model. Although iodide

uptake by the thyroid in healthy infants functions at a level similar to adults, this assumption that a decrease of 2.2% is inconsequential does not provide the level of protection that is usually extended to clearly sensitive subpopulations. Critically, infants do not achieve complete maturity of thyroid function until 1-2 months postnatally, display a shorter thyroxine half-life, and do not have the same degree of thyroid reserve capacity as healthy adults (Brown et al., 2004; van den Hove et al., 1999; Zoeller and Rice, 2004). While most infants with severe thyroid problems are identified within a few days after birth, premature infants, infants with subclinical hypothyroidism or with low iodine intake are not represented by the average healthy infant considered by the PBPK model. Furthermore, the predictions for perchlorate exposure and decreases in iodide uptake are only averages for the group considered, normal healthy infants, and the range that could be predicted by the model due to differences in pharmacokinetic and pharmacodynamic factors is not given.

Comment: III (A)(3), pp 60268-9. The elegant PBPK model of Clewell et al. (2007) represents a significant advance in understanding potential perchlorate effects on the human maternal/fetal unit, and the maternal to infant passage of perchlorate and iodide through mother's milk. However, some of the parameters in this model are inadequately understood and documented. The adaptations utilized by EPA (U.S. EPA, 2008) appear to improve the model, but we are concerned that it may not sufficiently address fetal and infant iodide/perchlorate ratios and potential effects on thyroid hormone regulation. We believe that more review of the model and its interpretation are needed, especially considering potential inhibition of fetal iodide uptake in mothers with low iodide consumption (i.e., maternal/fetal variation).

Comment: IV (B)(5), pp 60277-9. PBPK modeling. Critical parameters such as relative transport of iodide and perchlorate across the placenta and uptake into fetal thyroid are not yet available. We therefore would judge these calculations and conclusions very cautiously.

For estimation of infant's exposure to formula on p. 60279, the EPA has referred to their new evaluation of the data from the 1994-96 and 1998 Continuing Survey of Food Intakes by

Individuals, by Kahn and Stralka, which was recently published online in the Journal of Exposure Science and Environmental Epidemiology. We note that the values cited from this source are less than we have been using, based on EPA (2004), but we have not had the opportunity to compare the evaluations and strength of conclusions in detail.

Comment: Third, in particular, the PBPK model referenced in the letter has already been extensively peer-reviewed. Furthermore, the EPA is conducting an independent external letter peer review of a draft report prepared by EPA's Office of Research and Development titled, Inhibition of the Sodium-Iodide Symporter by Perchlorate: An Evaluation of Lifestage Sensitivity Using Physiologically-based Pharmacokinetic (PBPK) Modeling. This review is expected to be completed shortly. The underlying model and its expansions are already the subject of four peer-reviewed, published scientific articles.[FN5: Rebecca A. Clewell et al., The Use of Physiologically-Based Models to Integrate Diverse Data Sets and Reduce Uncertainty in the Prediction of Perchlorate and Iodide Kinetics Across Life Stages and Species, Toxicol. Ind. Health, 2001, 210-222; Rebecca A. Clewell et al., Predicting Fetal Perchlorate Dose and Inhibition of Iodide Kinetics During Gestation: A Physiologically-Based Pharmacokinetic Analysis of Perchlorate and Iodide Kinetics, 2003, Toxicol. Sci., 2003, 235-55; Elaine A. Merrill et al., PBPK Model for Radioactive Iodide and Perchlorate Kinetics and Perchlorate-Induced Inhibition of Iodide Uptake in Humans, Toxicol. Sci., 2005, 25-43; Rebecca A. Clewell et al., Perchlorate and Radioiodide and Kinetics Across Life Stages in the Human: Using PBPK Models to Predict Dosimetry and Thyroid Inhibition and Sensitive Subpopulations Based on Developmental Stage, J. Toxicol. Envtl Health, 2007, 408-28.] Significantly, the NAS panel endorsed it as "the best available approach" for determining effects in sensitive subpopulations where experimentation is impossible. While we are not aware of the particular changes EPA staff made to the PBPK model for use in the preliminary determination, the Federal Register notice provides an estimate of predicted changes in iodine uptake inhibition (IUI) in sensitive subpopulations that do not differ significantly from the published findings in Clewell et al. (2007). The results of this modeling estimate that certain sensitive populations (although not the most sensitive population, which are pregnant women and their fetuses) may have exposures in excess of the RfD. However, these groups would have minimal IUI at environmental doses. These conclusions are important enough to state again: even at doses greater than the reference dose, sensitive subgroups within the population may have minimal changes in their IUIs. The magnitudes of these changes are small enough to be attributable to normal fluctuations, possibly from diet. As noted by the NAS review, unless there is a sustained and significant change in IUI, adverse effects from perchlorate will not occur.[FN6: See Note 1.]

EPA Comment ID: 20950
EPA Comment Code: 2400

Comment: A major concern is that the application of the PBPK model after the establishment of an RfD is a novel concept that must be thoroughly vetted prior to using in the regulatory setting. EPA should convene a peer review process to evaluate this novel use of a PBPK model, not just for use in developing a health advisory level for perchlorate, but its use in the general sense. Such deviations from the standard risk-based approaches must be thoroughly evaluated, with recommended applications and limitations clearly identified.

Comment: 3. EPA ignores fails to adequately consider evidence that the proposed HRL is not safe

Although EPA's scientific staff issued a rigorous review of the PBPK model and its findings, the Agency has ignored the most important conclusions of the report, that infants and young children will have a perchlorate intake that exceeds the RfD. Instead, the preliminary determination seems to suggest that the PBPK model results support the Agency's proposed HRL. This is not the case.

A. The PBPK model provides evidence that at the proposed HRL, infants and young children will have a perchlorate intake that exceeds the reference dose.

The EPA scientific staff conducted a rigorous evaluation of the application of the physiologically-based pharmacokinetic (PBPK) model, particularly as it applies to sensitive life-stages.[FN49: EPA Office of Research and Development. Inhibition of the sodium-iodide symporter by perchlorate: An

evaluation of lifestage sensitivity using physiologically-based pharmacokinetic (PBPK) modeling. Preliminary Draft. October 2, 2008. EPA/600/R-08/106A. Docket ID No. EPA-HQ-OW-2008-0692-0076.] On October 2, 2008, EPA issued the report, which identifies some very troubling findings, including evidence that consuming water that was contaminated at the HRL of 15 ug/L would lead to bottle-fed infants exceeding the reference dose by 5-fold and young children exceeding the reference dose by 2.8-fold, based on average food contamination rates, average body weights, and 90th percentile water consumption rates for each age group (Staff Report, Table 4).[FN50: EPA Office of Research and Development. Inhibition of the sodium-iodide symporter by perchlorate: An evaluation of lifestage sensitivity using physiologically-based pharmacokinetic (PBPK) modeling. Preliminary Draft. October 2, 2008. EPA/600/R-08/106A. Docket ID No. EPA-HQ-OW-2008-0692-0076.] Specifically, the staff report found that the PBPK model predicted the perchlorate intake (ug/kg-day) from average food consumption, and 90th percentile water consumption held to 15 ug/L perchlorate as shown in Table 1. The table also identifies the magnitude by which the RfD is exceeded at the proposed HRL.

[Table 1: Perchlorate intake at a Health Reference Level of 15 ug/L - see PDF Docket ID EPA-HQ-OW-2008-0692-????]

These values were also reported in the Federal Register notice, Table 8.[FN51: 73 Fed. Reg. at 62078.] Note that the overwhelming majority of perchlorate for these age groups is coming from water or breast milk, and not from solid food. These data, generated from the PBPK model predictions, provide substantial scientific support for the conclusion that infants (both breast- and bottle-fed) and young children would exceed the reference dose if their dietary water were contaminated with perchlorate at the HRL.

EPA Comment Code: 2400

Comment: B. PBPK model supports an uncertainty factor of at least 15-fold

EPA normally uses a 10-fold default uncertainty factor to adjust for variations among individuals, called the intraspecies factor, when the Agency lacks adequate data to calculate intra-individual variability. EPA used this 10X intraspecies factor for its perchlorate hazard assessment on its IRIS database: "An intraspecies uncertainty factor of 10 is applied to protect the most sensitive population, the fetuses of pregnant women who might have hypothyroidism or iodide deficiency."[FN58: EPA. IRIS database. Perchlorate and perchlorate salts. http://www.epa.gov/ncea/iris/subst/1007.htm#revhis] The Agency has adopted the practice of describing the default 10-fold intraspecies factor as being comprised of the product of two 3-fold factors, one for pharmacokinetic variability, and the other for pharmacodynamic variability.[FN59: US EPA. Office of the Science Advisor: Staff Paper, Risk Assessment Principles & Practices. Page 69, Section 4.3.2. EPA/100-B-04/001. March, 2004. http://www.epa.gov/osa/pdfs/ratffinal.pdf] Pharmacokinetics describes the way that a compound such as perchlorate moves through the body,

including its absorption, distribution, metabolism and excretion. In contrast, pharmacodynamics describes what the compound does in the body, including depressing, stimulating, irritating, or killing cells or systems.

According to the IRIS glossary of terms, a PBPK model estimates the dose of a compound to a target organ or tissue by calculating the rate of absorption in the body, the distribution among target organs, the metabolism of the compound, and the excretion of the compound.[FN60: IRIS Glossary. Physiologically Based Pharmacokinetic (PBPK) Model. http://www.epa.gov/ncea/iris/help_gloss.htm#p] In other words, the PBPK model, by definition and design, estimates the pharmacokinetics of a compound.

The data from EPA's staff report however, shows that EPA's reliance on a default uncertainty factor of 10 underestimates the variability between fetuses and adults. The Executive Summary of the staff report states that "at a perchlorate dose of 7 ug/kg-day [the RfD], the percent RAIU inhibition predicted by the model for the near-term fetus is 5-fold greater than the average adult...The same analysis predicts percent RAIU inhibition approximately 1-2 fold higher for the breast-fed and bottle-fed infant (7-60 days) than for the average adult."[FN61: See EPA Staff Paper, Table 3; see also 73 Fed. Reg. 60278.] More specifically, for perchlorate, the variability between a near-term fetus (40 weeks gestation) and an adult is 5.3-fold, Therefore, the PBPK model supports a pharmacokinetic adjustment factor of at least 5-fold.

The Agency has no information from the PBPK model, or from other data, to develop an intraspecies uncertainty factor for pharmacodynamic variability, particularly between adults and sensitive lifestages. Therefore, EPA should retain a 3-fold default factor for pharmacodynamic uncertainty, consistent with its current practice.

Using the data from the PBPK model to support a pharmacokinetic intraspecies variability factor of 5, and the lack of pharmacodynamic data to support a default factor of 3, then the total intraspecies uncertainty factor should be (5 x 3) 15-fold, which is consistent with EPA policy and practices, and is supported by the available data.

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination. The modeled estimates of alternative HRLs reflect only pharmacokinetics and do not consider uncertainty due to pharmacodynamics. Pharmacodynamics is dose description of the dose-dependent effect of a chemicals on the target organ. Pharmacodynamics may vary by life stage.

Comment: 3. Your letter also raises a concern that the PBPK model has been only validated in adult humans and rat pups, not in infants and children, adding that use of rat data to project pharmacokinetics to human newborns is uncertain given the differences in the rate of development of clearance mechanisms between rodents and humans.

PBPK modeling is the best method today to address sensitive populations when testing is not possible or ethical. In fact, the PBPK model referenced has already been extensively peer reviewed, including via modeling conducted on sensitive populations.

To be specific, the underlying model and its expansions are the subject of four peer-reviewed, published scientific articles [FN1: Rebecca A. Clewell et al., The Use of Physiologically-Based Models to Integrate Diverse Data Sets and Reduce Uncertainty in the Prediction of Perchlorate and Iodide Kinetics Across Life Stages and Species, Toxicol. Ind. Health, 2001, 210-222; Rebecca A. Clewell et al., Predicting Fetal Perchlorate Dose and Inhibition of Iodide Kinetics During Gestation: A Physiologically-Based Pharmacokinetic Analysis of Perchlorate and Iodide Kinetics, 2003, Toxicol. Sci., 2003, 235-55; Elaine A. Merrill et al., PBPK Model for Radioactive Iodide and Perchlorate Kinetics and Perchlorate-Induced Inhibition of Iodide Uptake in Humans, Toxicol. Sci., 2005, 25-43; Rebecca A. Clewell et al., Perchlorate and Radioiodide and Kinetics Across Life Stages in the Human: Using PBPK Models to Predict Dosimetry and Thyroid Inhibition and Sensitive Subpopulations Based on Developmental Stage, J. Toxicol. Envtl Health, 2007, 408-28.]. Further, EPA is conducting an independent external letter peer review of a draft report prepared by EPA's Office of Research and Development titled, Inhibition of the Sodium-Iodide Symporter by Perchlorate: An Evaluation of Lifestage Sensitivity Using Physiologically-based Pharmacokinetic (PBPK) Modeling. This review is expected to be completed shortly.

While we are not aware of the particular changes EPA staff made to the PBPK model for use in the preliminary determination, the Federal Register notice provides an estimate of predicted changes in iodine uptake inhibition (IUI) in sensitive subpopulations that do not differ significantly from the published findings in Clewell et al. (2007). The results of this modeling estimate that certain sensitive populations (although not the most sensitive population, which are pregnant women and their fetuses) may have exposures in excess of the RfD.

However, these groups would have no significant inhibition of IUI at environmental doses. These conclusions are important enough to state again: even at doses greater than the reference dose, sensitive subgroups within the population may have minimal changes in their IUIs. The magnitudes of these changes are small enough to be attributable to normal fluctuations, possibly from diet. The critical study chosen by the NAS to base its recommended RfD on, Greer et al. (2002) reported no IUI (1.8% $\pm$ 8.3) which was determined not to inhibit the first effect - a non adverse, fully reversible biochemical reaction - in the cascade of biochemical events. The PBPK modeling estimated that infants may have IUI as great as 2.2% at this dose, however, this value is well within normal variability and does not suggest that perchlorate is causing any inhibition of IUI that is different from Greer et al. (2002) and is supportive of other similar information regarding the affinity of perchlorate to the NIS.

As noted by the NAS review, unless there is a sustained and significant change in IUI, adverse effects from perchlorate will not occur.[FN2: National Academy of Sciences, Health Implications of Perchlorate Ingestion, 2005, at 165 (pdf version).]

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination. EPA agrees that the modifications to the Clewell (2007) model were peer reviewed and found to be sound. The peer review report can be found on EPA's website at http://water.epa.gov/drink/contaminants/unregulated/perchlorate.cfm.

Commenter Name: Michael Girard

EPA Comment ID: 21021
EPA Comment Code: 2400

Comment: 4. Also concerning PBPK Modeling, your letter suggests that EPA's application of the PBPK modeling is "unorthodox" in regulatory risk assessment because it should not be used to exceed an established RfD. However, EPA's use of the modeling is not used to exceed the RfD in this case, but rather to validate the benchmark of 15 ug/L as the HRL, and supports the point that the HRL derived by the Agency is even more health protective than the already conservative NAS-based RfD that has been adopted by EPA. EPA policy has been to use PBPK modeling for determining human equivalent exposures (HEEs) and adjusting default uncertainty factors [FN3: U.S. EPA Risk Assessment Forum, A Review of the Reference Dose and Reference Concentration Process, December 2002.] Significantly, the NAS perchlorate panel agreed with EPA in finding PBPK modeling is "the best available approach" in determining effects in sensitive populations where experimentation is impossible (NAS, 2005) [FN4: The NAS panel also concluded the following: "By applying factors for life-stage differences (such as pregnant or lactating female rat vs. adult male rat) and for species differences (such as adult rat vs. adult human or pregnant or lactating rat vs. pregnant or lactating human), one can constrain PBPK simulations by using known physiologic measures and biochemical constants to estimate HEEs in potentially sensitive populations that may not be suitable for experimental validation."] EPA personnel have co-authored studies involving PBPK modeling and perchlorate (Merrill et al., 2005) and present for this preliminary determination, a model from Clewell et al. (2007) that was modified by making coding changes which served to improve the predictability of the model and therefore its overall usefulness. With this modified model, EPA is able to predict doses and changes in RAIU in pregnant women, fetuses, infants, and young children.

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination. See response to comment code 5220 for a discussion of alternative health reference levels. The modifications to the Clewell (2007) model were peer reviewed and found to be sound. The peer review report can be found on EPA's website at http://water.epa.gov/drink/contaminants/unregulated/perchlorate.cfm.

EPA agrees that significant uncertainty in risk estimates remains whether or not the PBPK model is used. However, trading one uncertain estimation technique for another does not reflect progress unless the change sheds light on significant sources of uncertainty in the risk estimate. Given the incomplete nature of the PBPK model, i.e., the lack of representation of pharmacodynamics and differential life stage impact, and incomplete representation of pharmacokinetics, evaluating differential uncertainty between traditional approaches and the PBPK model referenced in the October 2008 FRN appears to have limited if any value.

EPA Comment Code: 2400

Comment: 2. Perchlorate and Human Health in 2008: The EPA Preliminary Determination. These comments include two sections. The first relates to scientific policy issues. Particular focus is placed on pharmacodynamic (PBPK) modeling. Several reports in the general circulation press have suggested incorrectly that PBK modeling is unfamiliar in perchlorate risk assessment. These comments document that the PBPK modeling has been recognized by EPA and endorsed by the NAS for its effectiveness in reducing scientific uncertainty.

These comments conclude with a review of the statutory criteria establishing EPA's authority in this proceeding. Citing the NAS report as well as subsequent studies, the comments demonstrate that the Agency is correct that none of the three criteria required for setting an NPDWR are met in this case.

Thank you for the opportunity to comment on these important issues. Please do not hesitate to contact me or Dr. Richard C. Pleus, if we can provide additional information or perspective in your deliberations.

Sincerely, Michael Girard Chairman, Perchlorate Study Group

Response: The commenter is correct that application of PBPK modeling to EPA risk assessments is increasing, and that it has the potential to inform estimation of adverse effects and dosimetry across a broad range of questions. See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination.

Comment: VII. The Published, Peer-Reviewed PBPK Model is Part of the Best Available Science EPA Can Use for the Determination

One uncertainty in the derivation of the HRL as well as in the literature database is the lack of studies that measure radioactive iodine uptake (RAIU) in the sensitive population, pregnant women and the developing fetus. Obviously, it would be unethical to conduct such as study. However, Physiologically Based Pharmacokinetic (PBPK) modeling has been found to be useful in reducing uncertainty and in filling scientific gaps in human health data on a substance. EPA policy has been to use PBPK modeling for determining human equivalent exposures (HEEs) and adjusting default uncertainty factors.[FN5: U.S. EPA Risk Assessment Forum, A Review of the Reference Dose and Reference Concentration Process, December 2002.] The NAS perchlorate panel agreed with EPA in finding PBPK modeling is "the best available approach" in determining HEEs (NAS, 2005).[FN6: The NAS panel also concluded the following: "By applying factors for life-stage differences (such as pregnant or lactating female rat vx adult male rat) and for species differences (such as adult rat vs adult human or pregnant or lactating rat vs pregnant or lactating human), one can constrain PBPK simulations by using known physiologic measures and biochemical constants to estimate HEEs in potentially sensitive populations that may not be suitable for experimental validation."] EPA personnel have co-authored studies involving PBPK modeling and perchlorate (Merrill et al., 2005)

and present for this preliminary determination, a model from Clewell et al. (2007) that was modified by making coding changes which served to improve the predictability of the model and therefore its overall usefulness. With this modified model, EPA is able to predict doses and changes in RAIU in pregnant women, fetuses, infants, and young children.

[Text Box: The utility of PBPK modeling has been previously recognized by EPA and has been endorsed by the NAS for use in reducing scientific uncertainty.]

Using a 90th percentile water intake and based on data specifically for a pregnant woman, the model predicted that,

...the pregnant woman's dose of perchlorate would not exceed the reference dose if she consumed drinking water with a concentration of 15 ug/L or less, which is consistent with the derivation of the HRL from the reference dose, but based on average body weight, 90th percentile water consumption, and 90th percentile food exposure for pregnant women. (73 FR 60280)

The model verified that exposures to 15 ppb of perchlorate in drinking water will not reduce RAIU significantly, even assuming concurrent exposure through food and water intake in the 90th percentile. This combination of high-end exposure assumption is highly unlikely, probably at the extreme end of the population distribution. For this hypothetical pregnant woman, the percent RAIU inhibition was 1.1%. The greatest inhibition was seen in 7 day old infants at 2.2%. These percent inhibitions are consistent with the 1.8% inhibition of iodine uptake from the Greer et al. (2002) No Observed Effect Level (NOEL). In fact, although 2.2% is greater than 1.8% found in Greer et al., (2002), it is well within the standard error from Greer et al. (2002) of 8.3% and would still constitute a NOEL. The NAS report noted that "the very small 1.8% decrease in thyroid radioiodide uptake identified in Greer was well within the normal variation, and therefore 1.8% IUI does not define the limit beyond which adverse effects occurs has has been incorrectly argued. The PBPK modeling is in accord with results from other corroborative studies, such as Tellez et al. (2005), which show no adverse effect on sensitive populations.

In summary, EPA's PBPK modeling supports the point that the HRL derived by the agency is even more health protective than the already conservative NAS-based RfD that has been adopted by EPA. The modeling provides scientific support that incorporating an additional level of conservatism in deriving an HRL is unnecessary as the RfD is already very conservative; based on this support, a National Primary Drinking Water Regulation would not provide a meaningful reduction in risk.

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination. .

The commenter is correct that application of PBPK modeling to EPA risk assessments is increasing, and that it has the potential to inform estimation of adverse effects and dosimetry across a broad range of questions. EPA also agrees that the modifications to the Clewell (2007) model were peer reviewed and found to be sound. The peer review report can be found on EPA's website at http://water.epa.gov/drink/contaminants/unregulated/perchlorate.cfm.

Comment:

Comments on Use of the Physiologically-Based Pharmacokinetic Model (PBPK) - ASDWA does not have any detailed comments to offer on the use of the PBPK model to evaluate or predict the health impact of perchlorate or about how this information could support a regulatory determination. State drinking water programs, with a few exceptions, do not have toxicologists or other health effect and risk analysis experts on their staffs to provide detailed evaluations of these issues. That is why very few states adopt their own regulatory standards but rely on EPA to set appropriate Maximum Contaminant Levels (MCLs). As stated earlier, ASDWA expects EPA to use sound scientific data from peer reviewed research to make regulatory determinations. States must explain to water systems and the public how the resulting MCLs protect public health and a strong scientific basis for the rule makes that justification credible. We do appreciate the rigor with which the Agency has explored this issue and the range of options being considered in connection with the PBPK model as well as the evaluation of the relative sensitivity of the various life stages to perchlorate exposure in drinking water.

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination.

Comment: Comment No. 4

Section III. 2. What Were the Key Scientific Issues Raised by Commenters

Page & Paragraph Page 41885 Col 1, Para 4 Col 2, Para 2

Comment EPA has issued several PBPK guidance documents, including Use of Physiologically Based Pharmacokinetic Models to Quantify the Impact of Human Age and Interindividual Differences in Physiology and Biochemistry Pertinent to Risk (EPA/600/R-06/014A) and Approaches for the Application of Physiologically Based Pharmacokinetic Models and Supporting Data in Risk Assessment (EPA/600/R-05/043F), and notes at its National Center for Environmental Assessment webpage (http://cfpub.epa.gov/ncea/cfm/recordisplay.cfm?deid=2044, accessed 15 September 2009), "Physiologically-based pharmacokinetic (PBPK) models have increasingly been employed in chemical health risk assessments carried out by the U.S. Environmental Protection Agency (EPA), and it is anticipated that their use will continue to increase." Given such activities and statements, it is not clear from the current notice, why the agency is now proposing removing the PBPK models from the evaluation of life-stage specific differences in susceptibility. In fact no reasons are given, other than a few commenter concerns about (1) the level of peer review and (2) the existence of uncertainty in the model parameters, neither of which provide a sound reason for discarding the models. This is particularly troubling given that EPA specifically released its final, peer-reviewed report on Inhibition of the Sodium-Iodide Symporter by Perchlorate: An Evaluation of Life Stage Sensitivity Using Physiologically Based Pharmacokinetic (PBPK) Modeling (EPA/600/R-08/106A) as supporting material for the19 August 2009 Federal Register notice (accessed on 15 September 2009 at the NCEA webpage http://cfpub.epa.gov/ncea/cfm/recordisplay.cfm?deid=212508#Download). In the document, EPA definitively concludes that with minor modifications proposed by the Agency the Clewell et al. (2007) and Merrill et al. (2005) PBPK models are acceptable to calculate the life stage differences in the degree of thyroidal NIS RAIU inhibition at a given level of perchlorate exposure.

Suggested Action, Revision and References (if necessary) It is recommended that the PBPK models continue to be used in the evaluation of perchlorate life- stage susceptibility.

Comment No. 5

Section III. 2. What Were the Key Scientific Issues Raised by Commenters

Page & Paragraph Page 41885 Col 1, Para 4

Comment The current documentation of the background for the development of the HRL gives significant weight to public comments regarding peer review of the models, which together with the lack of EPA response, gives the impression that the models have, in fact, escaped rigorous peer review. The background documentation suggests that peer review has been limited to eight experts and this is not the case.

Suggested Action, Revision and References (if necessary) It is recommended that the peer review of the models be appropriately documented. The PBPK models have undergone thorough, rigorous review by a variety of scientific panels comprised of experts from academia, regulatory agencies, the National Academies of Science, and independent consultants. Changes made to the original models by the EPA were independently reviewed by a panel of experts and deemed appropriate. Furthermore, while areas for improvement have been identified in each of the peer reviews, comments by the panels have always been positive and supportive of their intended use in identifying the susceptible life-stages for perchlorate inhibition.

Comment No. 6

Section III. 2. What Were the Key Scientific Issues Raised by Commenters

Page & Paragraph Page 41885 Col 2, Para 2

Comment As suggested in EPA (2009), there are indeed uncertainties in some of the model parameters, as there is always uncertainty in any calculation of risk. The benefit of using PBPK models is that the uncertainty in the calculations is more transparent than the typical default approach. For example, it is clear from evaluation of the model output that there is not enough data to adequately define exposure parameters (particularly in the young neonate) and urinary clearance parameters. By focusing on those model parameters with uncertainty, collection of the data needed to improve our knowledge and reduce uncertainty can be initiated. Furthermore, the effect of these model parameters on the predictions of inhibition can be explored. The fact that the overall predictions of inhibition across life-stages were not significantly changed despite the changes made to the model intake and clearance parameters by the EPA indicates that the models are robust within the potential range of parameters made available in the data. The models help to define and decrease the areas of uncertainty, rather than increase them, which is what happens when the models are removed from consideration and life-stage comparisons are made solely on estimates of average of upper bound estimate of food and water intake.

Suggested Action, Revision and References (if necessary) It is recommended that the PBPK models be utilized and the uncertainty analysis be performed appropriately.

Comment No. 7

Section III. 2. What Were the Key Scientific Issues Raised by Commenters

Page & Paragraph Page 41885 Col 2, Para 2

Comment Some of the uncertainty can be addressed through the use mathematical and statistical tools to estimate the effect of the parameter variability on model predictions. Using statistical tools such as Monte Carlo analysis, we can determine ranges of inhibition expected at proposed HRLs while taking into account variability in the parameters. Without the models, the uncertainty still exists. There is still a lack of data for exposure and clearance in the HRL approach but it is not as

obvious. Discarding the models does not eliminate uncertainty in lifestage dosimetry, but it is hidden within the additional uncertainty associated with the default calculations. Reverting to the default approach based on external exposure concentrations in media, does not improve the estimate of risk or increase the likelihood of protecting the public. Rather it allows the risk assessment to be driven by the data that is most readily available and easiest to explain than trying to deal with the more difficult task of incorporating the best available science. We do view this approach as scientifically defensible.

Suggested Action, Revision and References (if necessary) It is recommended that the PBPK models be utilized and the uncertainty analysis be performed appropriately.

Comment No. 8

Section III. 2. What Were the Key Scientific Issues Raised by Commenters

Page & Paragraph Page 41885 Col 2, Para 2

Comment The approach previously proposed for using the models to evaluate life-stage specific susceptibility to iodide uptake inhibition was a reasonable use of the models. They were not used to derive the HRL, but were used to verify that the recommended HRL was protective of all life-stages. Public comments and the subsequent revised proposal appear to imply that the previous calculations were performed using the PBPK models. This is not the case. According to the EPA (2008), the models were run to provide a second, independent test for the adequacy of the proposed HRL. This analysis was thoughtful, novel and informative to the level of risk associated with the proposed HRL. It is not clear why this approach was not followed in the current assessment, particularly in light of the subsequent completion and positive result of the PBPK model peer review.

Suggested Action, Revision and References (if necessary) It is recommended that the PBPK models be used in a reasonable approach.

Comment No.

Section III.A. 4. Request for Comment on Alternative Approaches. a., b., c.

Page & Paragraph Page 41886

Comment Clarity needs to be improved relative to presentation of the PBPK model results.

It also would be helpful if the uncertainties associated with the various alternative options, such as use of PBPK model (e.g., iodide status, and other data deficiencies) were compared with other suggested methods for developing health risk levels (e.g., using human data available from "direct measurement") in a tabular format, to help improve the clarity of the benefits/drawbacks of the alternative processes. For example, uncertainty was linked to the modeling code, the availability of data for the many variable parameters in the model, the combination and handling of the data

selected for use in simulations, and, in particular, the previous lack of human data for specific life stages including pregnant women and their fetuses, lactating women and their babies, and bottle-fed infants for which rat data were adapted. The inability of the model to reflect iodide nutritional status also was cited by three peer reviewers as an important limitation. Recent and available "direct measurement" data, as cited here, for sensitive lifestages should be evaluated for potential use in reducing these identified areas of uncertainty. This would also help identify areas for potential future research.

Suggested Action, Revision and References (if necessary) We recommend a tabular format of changes made to the EPA PBPK model in its last revision (May 2009) and the impact of those changes.

We recommend a tabular comparison of the impact on thyroid hormone levels from recent human data for perchlorate, thiocyanate, nitrate and iodide in healthy populations and additional modeling of these data to help determine the impact of low iodide for sensitive subpopulations, such as pregnant women and infants.

Category* E

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination.

The commenter is correct that application of PBPK modeling to EPA risk assessments is increasing, and that it has the potential to inform estimation of adverse effects and dosimetry across a broad range of questions. EPA also agrees that the modifications to the Clewell (2007) model were peer reviewed and found to be sound. The peer review report can be found on EPA's website at http://water.epa.gov/drink/contaminants/unregulated/perchlorate.cfm. However, the major reservation expressed was with the use of the model, not the validity of the internal calculations. EPA believes that the tabular comparison recommended above is an interesting approach that should be considered at such time as sufficient data to conduct a cumulative assessment for chemicals affecting the NIS receptor become available.

Commenter Organization: Nevada Division of Environmental Protection (NDEP)
EPA Document ID: EPA-HQ-OW-2009-0297-0638
EPA Comment ID: 28744
EPA Comment Code: 2400

Comment: The NDEP recommends that the EPA incorporate the following key concepts into the decision-making process, as explained more fully in the attached comments:

1. Additional clinical data are needed to help refine the PBPK model. Data are needed for adults, including pregnant women, and for neonates concerning thyroidal iodine capacity and the effects of sodium-iodide symporter (NIS) upregulation on thyroidal iodine uptake and/or thyroxine levels. Also, additional studies of other adults are needed to evaluate the effects of temporary iodine deficiency and NIS upregulation on perchlorate competitive inhibition of thyroidal iodine uptake and/or free thyroid hormone levels. This additional research would provide useful data to consider

in further refining the PBPK model to accurately reflect the effects of iodine deficiency in pregnant women, fetuses and neonates.

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination. EPA plans to continue to evaluate the best available science on perchlorate in preparing a proposed maximum contaminant level and goal for perchlorate.

EPA Comment Code: 2400

Comment: REQUEST FOR COMMENTS ON ALTERNATIVE APPROACHES

a. Using the PBPK model to evaluate the relative sensitivity of life stages to perchlorate exposure in drinking water

NRDC Response: The PBPK model can be used to evaluate life stage sensitivity, and it provides evidence that at the proposed HRL of 15 ppb, infants and young children will have a perchlorate intake that exceeds the reference dose.

The EPA scientific staff evaluated the application of the PBPK model, particularly as it applies to sensitive life-stages.[FN26: EPA Office of Research and Development. Inhibition of the sodium-iodide symporter by perchlorate: An evaluation of lifestage sensitivity using physiologically-based pharmacokinetic (PBPK) modeling. Preliminary Draft. October 2, 2008. EPA/600/R-08/106A. Docket ID No. EPA-HQ-OW-2008-0692-0076] On October 2, 2008, EPA issued the staff report on this evaluation, which identifies some very troubling findings, including evidence that consuming water contaminated at the HRL of 15 ug/L (or ppb) would lead to bottle-fed infants exceeding the RfD by 5- fold and young children exceeding the RfD by 2.8-fold, based on average food contamination rates, average body weights, and 90th percentile water consumption rates for each age group.[FN27: EPA Office of Research and Development. Inhibition of the sodium-iodide symporter by perchlorate: An evaluation of lifestage sensitivity using physiologically-based pharmacokinetic (PBPK) modeling. Preliminary Draft. Table 4. October 2, 2008. EPA/600/R-08/106A. Docket ID No. EPA-HQ-OW-2008- 0692-0076.] Specifically, the PBPK model predicts that the RfD is exceeded for infants and children at the originally proposed HRL of 15 ppb, at 90th percentile water intake. (See Table 1 below). The table also identifies the magnitude by which the RfD is exceeded at EPA's originally proposed HRL of 15 ppb.

Table 1: Perchlorate intake from water at 15 ppb, with and without food intake, at 90th percentile water intake (L/day) [See PDF docket ID EPA-HQ- OW-2009-0297-0412]

These perchlorate intake values were also reported in the October 10, 2008 FR notice in Table 8.[FN29: 73 Fed. Reg. at 62078.] Note that the overwhelming majority of perchlorate for these age groups comes from water or breast milk, and not from solid food. These data, generated from the PBPK model predictions, provide substantial scientific support for the conclusion that infants (both breast- and bottle-fed) and young children would exceed the RfD if their dietary water were contaminated with perchlorate at the originally proposed HRL of 15 ppb.

Despite these conclusions, EPA announced its preliminary determination not to regulate perchlorate in drinking water. Although that FR notice did report the staff conclusions, it contradicted them by concluding that "EPA believes drinking water with perchlorate concentrations at or below the HRL of 15 ug/L is protective of all subpopulations."[FN30: Id. at 60280] EPA failed to provide any data to support its conclusion, which is contradicted by the results of PBPK modeling as reported by staff experts and in the preliminary determination.[FN31: EPA Office of Research and Development. Inhibition of the sodium-iodide symporter by perchlorate: An evaluation of lifestage sensitivity using physiologically-based pharmacokinetic (PBPK) modeling. Preliminary Draft. October 2, 2008. EPA/600/R-08/106A. Docket ID No. EPA-HQ-OW-2008-0692-0076.]

Comment: Section III Alternative Approaches to Analyzing Scientific Data Related to Perchlorate in Drinking Water

For a number of reasons we do not believe that sodium iodide symporter (NIS) inhibition predictions based on Physiologically-Based Pharmacokinetic (PBPK) modeling should, at this time, be relied upon to establish or justify a perchlorate reference dose (RfD) nor to evaluate relative sensitivities between life-stages. Although the PBPK model previously relied upon, but now under reconsideration by EPA, provides a valuable exploratory research tool and is a potentially useful predictor of perchlorate distribution and NIS effects in the adult, it is highly uncertain regarding the fetal and neonatal life-stages of most concern and may not reflect perchlorate effects on thyroid function. Our view on this issue is based on the following observations:

1) In response to peer review comments on the PBPK models, EPA noted that "the models have not been specifically parameterized to describe hypothyroid or iodine deficient individuals." In other words the model does not take into account responses in those with insufficient iodine intakes, the very group of most concern with respect to perchlorate exposures. In other documents EPA has also noted that the PBPK model did not account for within group variability in pharmacokinetics; uncertainty in several model parameters, including fetal and neonatal values derived from rodent models, and differences in adaptive responses. Although peer reviewer comments recommended that a much more robust uncertainty analysis be preformed on the model, EPA concluded that this was beyond the scope of the current effort and would be difficult to conduct due to data gaps. However, such an assessment is critical to determining the ultimate usefulness of the model predictions.

2) The perchlorate associated thyroid hormone alterations reported in Blount et al. 2006 and Steinmaus et al. 2007 in women with urinary iodine < 100 ug/L highlight some of these uncertainties, as they suggest that either the model estimates of iodide uptake inhibition (IUI) at low

perchlorate intake levels are inaccurate; that unexpectedly small increments in IUI may cause thyroid effects; and/or that perchlorate may act through additional mechanisms not captured in current models. Although NIS inhibition has been viewed as perchlorate's primary mode of action, other possible mechanisms that could contribute to its toxicity have been suggested. Based on a biologically-based dose response model of the hypothalamus-pituitary-thyroid axis and PBPK modeled perchlorate distribution and inhibition of thyroid iodide uptake, a recent assessment concluded that IUI was insufficient to explain observed changes in rat thyroid hormone levels attributable to perchlorate (McLanahan et al. 2009). These results suggest either that an additional mechanism of action exists, perhaps attributable to perchorate uptake into the thyroid and interference with other targets involved in hormone synthesis and release or that the PBPK modeling is inaccurate.

3) Although the impact of thyroid toxicants on the fetus can be buffered by the thyroid hormone synthesis and reserve capacities of the mother, iodide insufficiency and pregnancy-related stresses on maternal thyroid function increase the potential for perchlorate effects during fetal development (Glinoer 2001; Ginsberg et al. 2007). These are factors that the PBPK modeling does not adequately account for and could lead to a significant underestimate of NIS inhibition.

4) Available data indicate that neonatal exposures to perchlorate in breast milk are significant. The median perchlorate exposure to two week old nursing infants in the U.S. was predicted to be 0.206 ug/kg/day (95th percentile = 0.744 ug/kg/day) (Ginsberg et al. 2007). Other data indicate that nursing infant perchlorate exposures in the U.S. can be even higher. Based on a breast milk intake rate of 0.172 L/kg/day and reported median breast milk perchlorate concentrations (Kirk et al. 2005 and 2007; Pearce et al. 2007a), we estimate that nursing infant perchlorate intakes in three U.S. cohorts ranged from 0.56 to 1.57 ug/kg/day. Dasgupta et al. (2008) estimated breast milk perchlorate intake rates ranging from 0.3-2.1 ug/kg/day, with intakes of 9 of 13 infants exceeding the National Research Council's (NRC) RfD (NRC 2005) (Dasgupta et al. 2008).

Due to the significance of this exposure pathway, PBPK modeled estimates of perchlorate and iodide concentrations in breast milk warrant close scrutiny and additional validation. In response to peer review comments, EPA added section 4.1.1 to the May 2009 report, "Inhibition Of The Sodium-Iodide Symporter By Perchlorate: An Evaluation Of Life Stage Sensitivity Using Physiologically Based Pharmacokinetic (PBPK) Modeling." This section includes several informative comparisons of model predictions with published data but no comparison of predicted human breast milk perchlorate concentrations with published data. A comparison of breast milk data from Pearce et al 2007; Kirk et al 2005 and 2007 etc. combined with estimated US median perchlorate intakes (Blount et al 2006) should be completed, as this would provide important insight into model uncertainty regarding this critical exposure pathway.

LIST OF FIGURES

EXECUTIVE SUMMARY

On August 19, 2009, the Environmental Protection Agency (EPA) issued a Federal Register (FR) notice requesting comments on alternative approaches to analyzing data related to EPA's perchlorate regulatory determination (the Notice; U.S. EPA, 2009b). The Notice says that "these additional comments are sought in an effort to ensure consideration of all the potential options for evaluating whether there is a meaningful opportunity for human health risk reduction of perchlorate through a national primary drinking water rule."

The following four points summarize the response prepared by Intertox on behalf of the Perchlorate Study Group (PSG).

1. Interpretation of physiologically-based pharmacokinetic (PBPK) modeling: The use of scientifically derived PBPK models is the best scientific approach among all alternatives for evaluating the relative sensitivity of different life stages, consistent with the conclusions of EPA's peer reviewers and the National Academy of Sciences National Research Council (NRC). The current EPA PBPK model for perchlorate, however, uses values for some key parameters (e.g., urinary clearance) that are not supported by the scientific evidence. The model also does not account for up-regulation of the sodium iodide symporter (NIS). As a result, the model does not provide the best scientific estimates of iodide uptake inhibition (IUI) that would be associated with a particular perchlorate dose, and likely overestimates IUI from perchlorate exposure for various life stages. Further, input parameters are not selected from consistent points within their distributions, such that it is unclear whether the model output represents low, average, or upper-bound estimates of possible IUI. Nonetheless, the predicted levels of IUI in the Notice are low and would be indistinguishable from fluctuations resulting from differences in diet and feeding styles. No adverse health concern at any life stage would be expected based on exposure to perchlorate at the point of departure dose (7 ug/kg-d). EPA should revise this model to represent science-based accurate information on PBPK parameters and use the results to determine whether regulation is necessary.

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination.

EPA Comment Code: 2400

Comment: A Interpretation of the Physiologically Based Pharmacokinetic (PBPK) Modeling

Properly conducted, PBPK models provide accurate, peer reviewed scientific information to reduce uncertainty about sensitive life stages. PBPK models for perchlorate have been under development for a number of years. In its 2005 assessment of perchlorate, the NRC identified several subpopulations that are potentially more sensitive than average adults to thyroid effects from perchlorate exposure, including pregnant women, fetuses, and infants, based in part on perchlorate PBPK models for pregnant and lactating rats and rat pups and adult humans. After the NRC evaluation, the perchlorate PBPK model was improved to include pregnant women, the fetus, lactating women, and the neonate, and was published in the peer reviewed literature (Merrill et al., 2005; Clewell et al., 2007).

Regarding the preliminary regulatory determination for perchlorate, EPA evaluated published PBPK models for perchlorate "based on their ability to provide additional information surrounding this critical effect for potentially sensitive subgroups and reduce some of the uncertainty regarding the relative sensitivities of these subgroups" (U.S. EPA, 2008a). EPA used public comments on the preliminary regulatory determination, as well as comments from an external peer review (Eastern Research Group, 2008), to further refine the model which is based on both pharmacokinetics and pharmacodynamics (U.S. EPA, 2009a) and used it to predict the relative RAIU inhibition for 17 distinct populations or life stages, including pregnant and lactating women, the fetus, and the neonate, assumed to be exposed to 0.007 mg/kg-d in drinking water. The results of this evaluation are presented in Table 1 of the Notice. From these results, EPA concluded that "by protecting the

fetus of the hypothyroid or iodide-deficient woman from the effects of perchlorate on the thyroid, all other life stages and subgroups would be protected."

EPA requested comments on three general questions regarding its use of the PBPK model as an alternative approach to assessing the relative sensitivity of different exposure populations. Responses to these questions follow. Note that the responses to Questions 1 and 2 are combined, as the questions are not substantively different.

1. EPA requests comment on using the PBPK model to evaluate the relative sensitivity of the various life stages to perchlorate exposure in drinking water.

2. EPA requests comment on the utility of the PBPK model for predicting the impact of different perchlorate drinking water concentrations on sensitive life stages to inform HRL selection.

Response: See response to comment code 2300 for a discussion of PBPK modeling in this regulatory determination.EPA does not agree that the model used in the 2008 preliminary determination reflects both pharmacokinetics and pharmacodynamics. The model reflects a subset of pharmacokinetic parameters for various life stages. Pharmacodynamics is dose description of the dose-dependent effect of a chemicals on the target organ. Pharmacodynamics may vary by life stage. The model depends upon the current RfD as an expression of the adverse effects of perchlorate, and any expression of pharmacodynamic variability is limited to some portion of the 10X uncertainty factor for intraspecies variability. The RfD was developed using data from adults, none of whom were pregnant. As such, it cannot reflect the potential variability among life stages due to pharamacodynamics. Data do not exist to describe the pharmacodynamic variability among life stages for perchlorate.

Commenter Name:
Commenter Organization: Intertox, Inc.
EPA Document ID: EPA-HQ-OW-2009-0297-0662
EPA Comment ID: 28881
EPA Comment Code: 2400

Comment: PBPK modeling is valuable as it can integrate dozens of experimentally derived variables drawn from peer reviewed scientific studies to characterize chemical absorption, distribution, metabolism, excretion, and toxicity/effect. PBPK modeling is well established in the pharmacological and toxicological sciences, where it has been used for more than 80 years to understand the action of chemicals in the body. More recently, PBPK models have been used in filling scientific gaps in human health data, especially when conducting animal studies is infeasible, unethical, or impractical.

As stated by Mager et al. (2003) in a review of the use of PBPK models:

The resolution of PK/PD [pharmacokinetic/pharmacodynamic] models and parameters is best achieved by having relevant pharmacokinetics..., an understanding of the mechanism of action of the drug, appreciating the determinants of any time dependence in responses, and collecting a suitable array of experimental measurements as a function of dose and time. When possible, such measurements should be sensitive, gradual, quantitative, reproducible, and meaningful.

This statement reflects scientific consensus about how scientific information should be used in a PBPK model. The EPA PBPK model is for the most part based on this philosophy and can be useful for informing risk management decisions. Not all parameters in this model, however, meet the criteria required for robust and predictive PBPK modeling. To be useful, the PBPK model inputs should be transparent and scientifically based. This would advance the overarching science policy articulated by the current EPA Administrator, Hon. Lisa Jackson.[FN8: EPA Administrator Lisa Jackson, in her May 9, 2009 memorandum on scientific integrity stated, "While the laws that EPA implements leave room for policy judgments, the scientific findings on which these judgments are based should be arrived at independently using well-established scientific methods, including peer review, to assure rigor, accuracy, and impartiality. This means that policymakers must respect the expertise and independence of the Agency's career scientists and independent advisors while insisting that the Agency's scientific processes meet the highest standards of rigor, quality, and integrity" (http://www.epa.gov/Administrator/scientificmemo.html)]

While supportive of a science based PPBK model, an evaluation of the EPA PBPK model reveals that model does not produce the best and most scientific estimates of IUI. For example, some components of EPA's PBPK model for perchlorate are not supported by the scientific literature and result in IUI predictions that do not reflect best scientific estimates of IUI associated with a particular perchlorate dose. In particular, EPA's uses values for one of the key parameters in the PBPK model, the urinary clearance of perchlorate, that are not supported by the scientific literature.[FN9: Per EPA's evaluations, perchlorate PBPK model predictions are highly sensitive to urinary clearance rate, such that changes in it significantly impact predicted RAIU inhibition for a particular life stage and perchlorate dose. For each of the 17 distinct populations or life stages evaluated in the model, EPA used one of two different urinary clearance values: 0.05 L/h-kg for the pregnant woman at gestational weeks 13, 20, and 40 (which also impacts the RAIU prediction for the fetus at gestational week 40), and 0.13 L/h-kg for all other populations/life stages. If one calculates urinary clearance in L/h by multiplying these values by the corresponding scaled body weight, the resulting urinary clearance rates for the pregnant woman are much lower than for all other adults evaluated by the model: urinary clearance rates range from 1.20 to 1.32 L/h for the pregnant woman, 3.21 to 3.28 L/h for the lactating woman, 3.08 L/h for the woman of child-bearing age, and 3.15 L/hr for the average adult. The assumption of reduced urinary excretion during pregnancy, however, is not supported by the bulk of the scientific literature. The perchlorate urinary clearance rates used in the model are based on data collected in Greer et al. (2002). These values were originally described in the Merrill et al. (2005) model for adult humans, and were incorporated into the Clewell et al. (2003a, 2003b, 2007) models. Per Merrill et al. (2005), the 0.13 L/h-kg clearance rate is based on the mean "fit" urinary clearance rate for perchlorate for adult males and females (nonpregnant) in the Greer et al. (2002) study; the values for the 23 individuals in that study ranged from 0.06 to 0.24 L/h-kg. According to Clewell et al. (2007), the 0.05 L/h-kg urinary clearance value applied to the pregnant woman (and fetus) was selected from the lower bound of this range, in part because this lower value was consistent with data from a study of perchlorate-exposed pregnant women in Chile (Tellez et al., 2005). Clewell et al. (2007) describes their rationale as follows: In the nonpregnant adult model, Merrill and coauthors (2005a) fitted the perchlorate urinary clearance value to each individual for which data were available and noted a marked variation between subjects. Values for urinary clearance (ClUcp) ranged from 0.05 to 0.24 ng/L-h [sic], with an average of 0.13 ng/L-h [sic]. Using the lower bound of these values (0.05 ng/L) [sic], the gestation model predicted serum levels were within the range of the experimental values of Tellez et al. (2005)... Since the lower clearance value lies within the range of the normal adult, improves the perchlorate prediction, and yields a more conservative estimate of risk, it was

used for all subsequent maternal simulations and dose metric calculations. Note that the actual lower bound of the perchlorate urinary clearance range from Greer et al. (2002) (reported in Merrill et al. (2005)) is 0.06 L/h-kg, not 0.05 L/h-kg. Further, this value of 0.06 L/h-kg is for an adult male; no pregnant women were included in the study population, and the lowest reported value for any woman is 0.09 L/h-kg. Clewell et al. (2007) indicated the lower-bound value from Greer et al. (2002) is consistent with data collected by Tellez et al. (2005). Tellez et al. (2005) evaluated perchlorate exposure in pregnant women in three cities in Chile exposed to perchlorate in water at average concentrations ranging from 0.5 to 114 ug/L. This paper says that urinary perchlorate was measured during two prenatal visits and one postnatal visit, and reported excretion in units of ug/L and ug/g creatinine. Unfortunately, no data are provided in the paper on time course of excretion, so it is unclear how Clewell et al. (2007) established that the lower bound of the urinary clearance rate for these populations was 0.05 L/h-kg. In selecting a urinary clearance value to use for the pregnant woman, EPA considered two additional values: clearance during pregnancy in the average adult based on Aboul-Khair et al. (1964); and clearance during pregnancy equal to nonpregnant average values. Aboul-Khair et al. (1964) evaluated urinary clearance of iodide in pregnant women in the United States and reported that "renal (urinary) clearance for iodide is elevated to as much as two times control (nonpregnant) values during pregnancy, and, while clearance then declines fairly rapidly towards control after birth, it is still elevated in the first couple of months" (U.S. EPA, 2009a). EPA assumed that urinary clearance of perchlorate would have the same pregnant to nonpregnant ratio reported by Aboul- Khair et al. (1964). EPA ran the model using all three values. Of these values, the clearance value used by Clewell et al. (2007) resulted in the highest predicted RAIU inhibition. For example, at a dose of 7 ug/kg-d (a dose ten times the RfD of 0.7 mg/kg-d), EPA (2009a) reports a RAIU inhibition for the fetus of 11% using the Clewell et al. (2007) clearance value, 5.2% using the average non- pregnant adult clearance value, and 3.4% using the Aboul-Khair et al. (1964) clearance value. Regarding final selection of this value, EPA (2009a) says: Since there are no conclusive human pregnancy data to distinguish which of these alternatives is more likely, EPA selected option 1, the lower clearance value reported in the peer-reviewed paper by Clewell et al. (2007) for relative response estimation (life stage sensitivity analysis), since this value leads to the most sensitive predictions... While this analysis uses the lowest urinary clearance value among the alternatives evaluated, it does not provide an overall upper-bound effect estimate because the impact of uncertainty and variability in parameters other than those examined here (e.g., uncertainty in thyroid NIS parameters and interindividual variability in urinary excretion) was not evaluated. Thus, EPA selected a urinary clearance value for this population based on a nonscience consideration that lacked corroborating data in the face of other data supporting a higher value. EPA states that selection of this value is not meant to reflect uncertainty or a bounded estimate. This is inconsistent with the statement in the Notice regarding the use of conservatism in the model (U.S. EPA, 2009a), that: The PBPK model for each life stage is presumed to represent a typical or average individual from that life stage. Thus, in evaluating specific PBPK parameter choices, especially for urinary clearance, EPA's objective was to ensure that the values appropriately represented an average or central value for a given life stage and age. EPA further elaborates (U.S. EPA, 2009a): In the case where more than one alternative clearance value appeared to be equally likely (i.e., had a similar quality and amount of supporting data), then the more "sensitive" option was selected (i.e., the option that leads to predictions of the highest sensitivity to perchlorate- induced RAIU). The overall analysis did not seek to select parameters associated with highest predicted effect and is not intended to represent an upper-bound estimate of the average effect of perchlorate in these populations. Modeling choices are assumed to represent the best or most likely (central) estimate for an average individual within the population. There is uncertainty about the average, and EPA has selected from within the range of uncertainty, but there is still expected to be population variability around the

model predictions based on that choice, with the model prediction being near the center of the distribution. The Notice states that the urinary clearance value was selected to "represent the best or most likely (central) estimate for an average individual within the population." Selecting the lowest urinary excretion value-one that produces the highest estimate of RAIU inhibition-is not the "average." The Notice declares that all three clearance values considered had a similar quality and amount of supporting data; in fact, this cannot be true based on the information presented. The 0.05 L/h-kg value was of low scientific quality (it is not supported by either source EPA cites as its primary basis, i.e., Greer et al. (2002) or Tellez et al. (2005)) and higher values are better supported by the scientific literature, as discussed below. The scientific literature shows that, although minimal, data are available on perchlorate urinary clearance or excretion rates during pregnancy, but do not suggest lower excretion of perchlorate during pregnancy. In the study of Chilean women, Tellez et al. (2005) reported higher urinary perchlorate excretion (measured as ug/g creatinine) during pregnancy relative to postpartum for women in two of the three cities evaluated (Chanaral and Taltal, which had mean concentrations of perchlorate in tap water of 5.8 and 114 ug/L). In the "low perchlorate" city (Antofagasta, with a mean tap water concentration of 0.5 ug/L), excretion was somewhat higher postpartum. Based on urine samples collected during the NHANES 2001-2002 study, Blount et al. (2007) reported higher urinary perchlorate in pregnant women (mean 3.27 ug/g creatinine, n = 115), relative to all women of reproductive age (mean 2.97 ug/g creatinine, n = 662). Interpretation of data on urinary clearance or excretion of iodide is complicated by the iodide status of populations; however, Smyth et al. (1997) reported that in an area of moderate iodine intake (median urinary iodide 82 ug/g creatinine), urinary iodide excretion was increased during all three trimesters of pregnancy relative to nonpregnant controls. EPA's selection of the lowest identified urinary clearance value for the pregnant woman and fetus is inconsistent with the statement in the Notice about the Agency's use of conservatism in the model (U.S. EPA, 2009a): The PBPK model for each life stage is presumed to represent a typical or average individual from that life stage. Thus, in evaluating specific PBPK parameter choices, especially for urinary clearance, EPA's objective was to ensure that the values appropriately represented an average or central value for a given life stage and age. EPA further states, "there is still expected to be population variability around the model predictions based on that choice, with the model prediction being near the center of the distribution," and: While this analysis uses the lowest urinary clearance value among the alternatives evaluated, it does not provide an overall upper-bound effect estimate because the impact of uncertainty and variability in parameters other than those examined here (e.g., uncertainty in thyroid NIS parameters and interindividual variability in urinary excretion) was not evaluated. Nonetheless, in practice, selection of the lowest urinary clearance value for two of the subpopulations renders the RAIU inhibition predictions for these populations more conservative than for other populations, making application of model results to risk assessment difficult to interpret from a purely scientific basis.]

In addition to using the best science to support PBPK values, other parameters could be added, such as up-regulation of the NIS. Up-regulation of the NIS represents an adaptive response to iodine deficiency in the thyroid, but EPA (2009b) did not incorporate a mechanism of up-regulation in the EPA model. Incorporation of NIS regulation into the model would more accurately reflect the probable response to perchlorate exposure in the environment.[FN10: Over the past decade, research regarding thyroid autoregulation and the regulation of expression of the NIS has proliferated. Evidence suggests that the NIS is up- regulated in response to iodine deficiency in the thyroid. Up-regulation of the NIS causes the number of NIS membrane proteins to increase; thus, when an individual is iodine deficient, the body increases the number of NIS "pumps" such that the thyroid is more effective at capturing iodide. This is a common adaptive mechanism that many

tissues, including the thyroid gland, use to maintain hormone homeostasis. The Draft EPA Office of the Inspector General (OIG) report (U.S. EPA 2008b) appears to consider up-regulation of NIS expression as well. Earlier versions of the model using the rat did consider up- regulation, and showed no RAIU inhibition in the rat thyroid after 18 days of exposure at perchlorate doses up to 10 mg/kg-d (350,000 ppb assuming default body weight and water intake) (Clewell et al., 2003a). Up-regulation was not included in the human model, "based on the fact that upregulation was not seen in the nonpregnant adult after 2 wk of doses as high as 1 mg ClO4- (Merrill et al., 2005)" and although "the current simulations cover lifetime exposures rather than a few weeks, the accompanying data on thyroid hormones (TSH, T4) still do not show evidence of thyroidal up-regulation (Crump et al., 2000; Tellez et al., 2005)" (Clewell et al., 2007). The NRC report, however, acknowledges the up- regulation of NIS expression, but did not incorporate it into their risk assessment. NRC (2005) states: ...rats compensated for the inhibition within 5 days of perchlorate administration, most likely by increasing the expression of NIS in the thyroid. The data suggest that compensation occurs more quickly in rats because rats have a smaller reserve capacity of thyroid hormones than humans.

Comment: Parameters used in the PBPK model were selected from inconsistent points within their distributions. For example, as described above, EPA (2009a) selected a lower bound value to describe the urinary clearance of perchlorate for the pregnant woman and fetus. In contrast, EPA reports that the urinary clearance values it selected for all other population subgroups fall in the middle of the range of possible values (U.S. EPA, 2009a). As a result, it is difficult to interpret the model output because it is unclear whether the output represents lower-, middle-, or upper- bound predictions of possible IUI caused by perchlorate exposure."[FN11: When conducting calculations to reflect exposure within a population, each parameter can have a range of possible values. In order for PBPK model output to be meaningful, the basis for selection of specific values within the range of possible values should be described and the relationship to the overall distribution for that parameter should be characterized (e.g., lower-bound, average, median, upper-bound). Further, in the absence of probabilistic assessment, if point estimates are selected for incorporation in the model, a consistent rationale should be applied in choosing values for the various parameters so that the location of the output within the overall distribution can be approximated. For example, when conducting baseline human health risk assessments for a reasonable maximum exposure (RME) scenario, EPA recommends estimating "a conservative exposure case (i.e., well above the average case) that is still within the range of possible exposures," and intake variable values for a given pathway should be selected so that the combination of all intake variables results in an estimate of the reasonable maximum exposure for that pathway (U.S. EPA, 1998a). The objective of evaluating conservative exposures is to generate an upper-bound estimate of exposure below which adverse health effects are unlikely. Note that although EPA presents the impact of alternative urinary clearance assumptions on model-predicted RAIU inhibition in its discussion document on the PBPK model (Table 4-2, U.S. EPA, 2009a), it does not present this information in the Notice.]

Comment: IV. CONCLUSIONS

1. The use of scientifically derived PBPK models represents the best scientific approach for evaluating the relative sensitivity of different life stages and to compare to occurrence data. As constructed, however, the perchlorate PBPK model likely overestimates IUI from perchlorate exposures for various life stages. Only when the best available science is shared in a transparent process can the public be empowered to assist the Agency in achieving the best public health decisions. Nonetheless, the predicted levels of IUI in the Notice are very low and would be indistinguishable from fluctuations resulting from differences in diet and feeding styles. No adverse health concern at any life stage would be expected based on exposure to perchlorate at the POD dose (7 ug/kg-d).

Comment: Specific issues on which USEPA requests comments in its August 18, 2009 notice are discussed below:

Interpretation and Application of Physiologically-based Pharmacokinetic (PBPK) Modeling

In the October 10, 2008 notice, the PBPK model was used to evaluate the effects of the proposed HRL, 15 ug/L, on the perchlorate dose reaching the thyroid and to estimate effects on the inhibition of thyroidal iodine uptake in sensitive subpopulations. It was assumed that the fetus of the pregnant woman was the most susceptible subpopulation, and our primary concern was that the exposure and health risks of bottle fed and breast fed infants and older children, as predicted by the PBPK model, were ignored.

Using 90th percentile water intakes, the PBPK model predicts that when water with 15 ug/L perchlorate is used to prepare formula, 7-day and 60-day old bottle-fed infants are exposed to more than 5 times the RfD, and that iodide uptake in 7-day old infants is decreased by 2.2% (Table 4-5). Exposures of 7-day and 60- day breast-fed infants and children 6-12 months and 1-2 years are also predicted to exceed the Reference Dose. Even if the model was to use the median rather than the

90th percentile water intake, the RfD would be greatly exceeded for bottle-fed infants. We recommend that USEPA consider the PBPK model's predictions of exposures and effects in these sensitive infants and children, as well as the exposure of the fetus through the pregnant mother, in evaluating the potential for perchlorate in drinking water to inhibit thyroidal iodine uptake.

Comment: However, there are several concerns that indicate the need for caution in using the PBPK model to determine a health-protective drinking water concentration for perchlorate. First, it is based on average weight babies and average weight healthy adults, including pregnant women. Furthermore, due to lack of availability of the needed data, only 40-week fetuses were considered and it was not possible to model effects on fetuses at earlier stages of development. Thus, the PBPK model may not adequately predict the effects of perchlorate on those who are particularly susceptible to its effects, such as low birth weight infants, mothers or infants with iodine deficiency or hypothyroidism, and fetuses younger than 40 weeks.

Comment: Response to questions posed by USEPA:

1) PBPK Modeling (page 41886)

ACWA does not take issue with this type of pharmacokinetic modeling. However, in previous regulatory determinations and drinking water standards, pharmacokinetic models were only used in a secondary fashion, if at all, after the toxic end point was identified by the relevant epidemiological data. We would like clarification on the justification for modifying existing procedures.

EPA Document ID: EPA-HQ-OW-2009-0297-0499
EPA Comment ID: 28930

EPA Comment Code: 2400

Comment: In this notice, the Agency specifically requests comments on certain approaches within their assessment, including the following:

1) Use of PBPK modeling analysis to inform the regulatory determination for perchlorate

2) Appropriateness of alternative health reference levels (HRLs) described in the notice to address and account for risk to all potentially sensitive life stages

3) Occurrence analysis including use of Bayesian model and U.S. Census data

Use of PBPK model: EWG supports the use of the PBPK model to estimate the extent of iodine uptake inhibition in sensitive life stages only if significant limitations of the current model are addressed.

In this notice, one of the approaches that the Agency considers is the following: "... use the PBPK modeling analysis to explore the relative sensitivity of the various life stages of concern to a fixed dose such as the point of departure (POD) or the reference dose (RfD)." In this case, the agency notes that the "POD is the lowest dose administered in the Greer et al clinical study...".

The Greer study included only 37 study participants who were divided into several study groups and administered different doses of perchlorate for 14 days (Greer et al 2002). The researchers determined that a daily perchlorate dose of 0.007 mg/kg/day was the no observed effect level (NOEL); the results from this study were used by the National Academy of Sciences (NAS) in setting the reference dose (RfD) for perchlorate of 0.7 ug/kg/day.

The Greer study results and assumptions drawn from them have been questioned in a peer-reviewed article that was published in Environmental Health Perspectives in 2005 (Ginsberg and Rice 2005). Two toxicologists, one from the Connecticut Department of Public Health and the other from the Maine Bureau of Health, conducted an analysis of the raw data from the Greer study and concluded the following: "Individual results of Greer et al. point to an effect in four of the seven individuals tested at the lowest dose (0.007 mg/kg/day), indicating that this dose is an effect level." In other words, while Greer et al. and the NAS both concluded that 0.007 mg/kg/day is a no observed effect level (NOEL), closer analysis of the data reveals that four of the seven study subjects in this group experienced effects at this dose, thereby invalidating 0.007 mg/kg/day as a NOEL.

The Massachusetts Department of Environmental Protection (Mass DEP), which has set the most stringent drinking water standard for perchlorate nationally, had the following observations about the Greer study:

"MassDEP has concerns about the lowest dose in the Greer study being a no-effect level based on the facts that: due to the small number of subjects in the lowest dose group, there is low power to detect a statistically significant effect; averaging of group responses obscures positive individual inhibition; a non- statistically significant IUI (iodine uptake inhibition) effect was observed at the lowest dose tested; and, good low dose corroborating data is lacking" (MassDEP 2006).

In light of these valid criticisms of the Greer study, it is clear that any exposure modeling based on the results of this study, including the agency's current proposal to use PBPK modeling with a POD derived from this particular study, would not be accurate. The PBPK model also does not address iodine status, an important factor in determining vulnerability to perchlorate (Blount et al 2006b).

Response: See response to comment code 2100 for a discussion of the Reference Dose for perchlorate. See response to comment code 2300 for a discussion of EPA's use of the PBPK models.

EPA Comment Code: 2410 Use of PBPK model to select life-stage-specific HRLs

Individual Comments

Commenter Name: Anonymous
Commenter Organization:
EPA Document ID: EPA-HQ-OW-2009-0297-0653
EPA Comment ID: 28558
EPA Comment Code: 2410

Comment: The Agency showed additional conservatism from the NRC recommendation in adjusting the preliminary guidance for perchlorate to 15 ppb in water in order to account for the relative source contributions of drinking water and dietary sources in order to protect pregnant women and their fetuses. This level, as demonstrated by the physiologically-based pharmokinetic (PBPK) modeling, is likewise protective of other potentially sensitive lifestages. The PBPK modeling for infants and young children do not exceed the 10x (i.e. ten fold) intraspecies factor set from the adult values thereby showing that the 10x intraspecies factor is protective and provides no justification for increasing an uncertainty factor for perchlorate beyond the default (i.e. ten fold or 10x). For this reason, EPA has no basis for adjusting the reference dose (RfD) of 0.0007 mg/kg/day, or the methodology for setting the HAL based on a 70 kg adult consuming two (2) liters of water. This traditional method, used previously by EPA with SDWA contaminants is sufficiently conservative as the level of water consumed (two liters) is the 99th percentile estimate, and, this RfD is based on a no-effect level (NOEL) from the Greer et. al. 2002 study rather than a no adverse effect level (NOAEL).

Response: EPA does not agree that allowance for contributions of perchlorate from sources other than drinking water introduces additional conservatism. Rather, allowance for other sources of perchlorate permits EPA to establish a concentration of perchlorate in drinking water that maintains a tolerable risk level without adjusting the existing background.

The modeled estimates of exposure to various life stages, presented as alternative HRLs in the August 2009 supplemental request for comments, indicate values as much as seven times that for pregnant females. However, the life stage variability in the model estimates reflects pharmacokinetics only. Pharmacodynamic variability is not reflected nor can it be estimated using the modified Clewell (2007) model. Data permitting estimation of pharmodynamic variability among life stages is not available. Therefore, it is not possible to determine whether the alternative HRLs are within the variability reflected in the RfD. EPA will continue to evaluate the significance of varying exposure estimates as the Agency develops a NPDWR for perchlorate.

Comment: b. EPA requests comment on the utility of the PBPK model for predicting the impact of different perchlorate drinking water concentrations on sensitive life stages to inform HRL selection.

Comment A.4.b.1: Additional refinement and supporting rationale for the current configuration of the PBPK model is needed based on actual human study observations to enable EPA to use this model for the stated purpose. This refinement should include an evaluation of the potential for sustained FT3 and/or FT4 reductions in humans including pregnant women, fetuses, and neonates. Human data (likely including reproductive age females and adolescents) on the pharmacokinetic use of perchlorate for lowering thyroxine levels in hyperthyroid patients are available in both published reports and likely also in clinical trials and unpublished data from various research groups. A critical step to support use of the PBPK model should include development of a quantitative term that defines the relationship between steady state blood perchlorate and the decrement in free and total thyroid hormones in reproductive age females. Much of the data needed for this refinement and supporting rationale are not currently available. Consequently, the EPA should send out queries searching for available unpublished human datasets relevant to the modeling evaluation, and encourage the development of appropriate studies to acquire these data and permit support for and use of the PBPK model.

One example of technical difficulties in the model is the consideration of iodine deficiency and associated NIS upregulation in the pregnant mother, fetus, and neonate. Additional clinical data are needed for adults (including pregnant women, and in neonates) concerning thyroidal iodine capacity and the impact of NIS upregulation on thyroidal iodine uptake and/or thyroxine levels. Also, additional studies of other adults are needed to evaluate the effects of temporary iodine deficiency and NIS upregulation on perchlorate competitive inhibition of thyroidal iodine uptake and/or free thyroid hormone levels. This additional research would provide useful data to consider in further refining the PBPK model to accurately reflect the effects of iodine deficiency in pregnant women, fetuses and neonates.

Response: See response to comment ID 28800 under comment code 2410.
EPA agrees that the PBPK model used in preparation of the 2008 Preliminary Regulatory Determination requires further refinement before it can be used to develop an HRL. EPA also agrees that the data required to permit the necessary modifications does not exist at this time. As additional data become available, EPA will be able to determine whether further effort to develop a PBPK model for different life stages exposed to perchlorate is warranted. The attributes and components of that model cannot be determined at this time.

EPA Comment Code: 2410

Comment: b. Utility of the PBPK model for predicting the impact of different perchlorate drinking water concentrations on sensitive life stages to inform the HRL

NRDC Response: The PBPK model can predict the impacts of perchlorate water contamination on different life stages; it predicts that sensitive populations are not protected by the proposed HRL

As detailed in our response above, the EPA staff report issued on October 2, 2008, describes findings from the PBPK model that consuming water that was contaminated at the HRL of 15 ug/L would lead to bottle-fed infants exceeding the reference dose by 5- fold and young children exceeding the reference dose by 2.8-fold, based on average food contamination rates, average body weights, and 90th percentile water consumption rates for each age group.[FN33: EPA Office of Research and Development. Inhibition of the sodium-iodide symporter by perchlorate: An evaluation of lifestage sensitivity using physiologically-based pharmacokinetic (PBPK) modeling. Preliminary Draft. October 2, 2008. Table 4. EPA/600/R-08/106A. Docket ID No. EPA-HQ-OW-2008- 0692-0076.]

These findings from the PBPK model analysis are supported by other published studies. A related study estimated perchlorate doses that correspond to urinary perchlorate excretion (hereinafter referred to as "Blount (2007)").[FN34: Blount BC, Valentin-Blasini L, Osterloh JD, Mauldin JP, Pirkle JL. Perchlorate exposure of the US Population, 2001-2002. J Expo Sci Environ Epidemiol. 2007 Jul;17(4):400-7. Epub 2006 Oct 18.] Calculating doses based on urinary excretion is feasible because perchlorate is not metabolized and has a short half- life of approximately 8 hours.[FN35: Ibid.] Blount (2007) showed that the adjusted geometric mean for perchlorate exposure in women was 0.059 ug/kg-day, and the 95th percentile exposure was 0.215 ug/kg-day. This means that the adverse effects of decreased serum T4 and increased TSH in women with low dietary iodide (that is, urinary iodide below 100 ug/L) described by Blount (2006) are occurring at perchlorate exposures below the RfD of 0.7 ug/kg- day.[FN36: Blount BC, Pirkle JL, Osterloh JD, Valentin-Blasini L, Caldwell KL. Urinary perchlorate and thyroid hormone levels in adolescent and adult men and women living in the United States. Environ Health Perspect. 2006 Dec;114(12):1865-71.] As such, the proposed HRL of 15 ppb will not protect sensitive subpopulations.

An extensive literature review and health assessment by Ginsburg et al.[FN37: GL Ginsburg, DB Hattis, RT Zoeller, and DC Rice. 2007. Evaluation of the U.S. EPA/OSWER preliminary remediation goal for perchlorate in groundwater: Focus on exposure to nursing infants. Environ Health Perspect. 115(3):361-369. http://www.ehponline.org/members/2006/9533/9533.html] published since the NRC review found that "drinking-water perchlorate must be < 6.9 ug/L to keep the median, and < 1.3 ug/L to keep the 90th-percentile nursing infant exposure below the RfD."[FN38: GL Ginsburg, DB Hattis, RT Zoeller, and DC Rice. 2007. Evaluation of the U.S. EPA/OSWER preliminary remediation goal for perchlorate in groundwater: Focus on exposure to nursing infants. Environ Health Perspect. 115(3):361-369.] Based on both exposure and toxicity information, and data on sensitive populations, the proposed HRL of 15 ppb, which is more than twice as high as the limit proposed by Ginsberg et al, will leave significant portions of the population at risk.

Response: EPA agrees that reassessing exposure assumptions and other life stages warrants further consideration.
EPA also considered applying the model directly to the exposures of other sensitive life stages to develop HRLs for these life stages. The NRC (2005) identified "the fetuses of pregnant women who might have hypothyroidism or iodide deficiency" as "the most sensitive population," but also identified infants and developing children as additional "sensitive populations." EPA derived potential alternative HRLs for 14 different life stages as presented in the supplemental request for comments (EPA 2009). Alternative HRLs are estimates of the maximum concentration of perchlorate that can be consumed in drinking water without an individual's total perchlorate dose

from food and water exceeding the RfD. EPA agrees that exposures reported in the literature suggest some life stages may be exposed to quantities of perchlorate above the RfD.

Comment: c. EPA requests suggestions for ways to use the PBPK modeling analysis to inform the regulatory determination for perchlorate that are different from those described in this notice or the October 10, 2008 notice.

Comment A.4.c.1: Prior to use of the PBPK model as a part of the regulatory determination, the range and primary sources of uncertainty in the model output should be evaluated and described. Once properly validated and supported, the model may be used to evaluate a number of physiological and pharmacokinetic impacts of perchlorate competitive inhibition, including alternative approaches of basing the reference dose on clinically important changes in thyroidal iodine uptake and/or thyroxine levels.

Response: The modified Clewell (2007) model was subjected to peer review by the Office of Research and Development, EPA. However, EPA agrees that additional modification and refinement of the model is needed before it can be used to develop an HRL to determine the need to establish an NPDWR. The extent and nature of modifications and refinements needed are not clear at this time.

Comment: c. Using the PBPK modeling analysis to inform the regulatory determination for perchlorate that is different from those described in the October, 2008 FR notice

NRDC response: The PBPK model may be used to derive a science-based adjustment factor; the model support an adjustment factor of at least 15-fold to inform the regulatory determination for perchlorate.

EPA normally uses a 10-fold default uncertainty factor to adjust for variations among individuals, called the intraspecies factor, when the Agency lacks adequate data to calculate variability between individuals. EPA used this 10- fold intraspecies factor for its perchlorate hazard assessment on its IRIS database: "An intraspecies uncertainty factor of 10 is applied to protect the most sensitive population, the fetuses of pregnant women who might have hypothyroidism or iodide

deficiency."[FN39: EPA. IRIS database. Perchlorate and perchlorate salts. http://www.epa.gov/ncea/iris/subst/1007.htm#revhis] The Agency has adopted the practice of describing the default 10-fold intraspecies factor as being comprised of the product of two 3-fold factors, one for harmacokinetic variability, and the other for pharmacodynamic variability.[FN40: US EPA. Office of the Science Advisor: Staff Paper, Risk Assessment Principles & Practices. Page 69, Section 4.3.2. EPA/100-B-04/001. March, 2004. http://www.epa.gov/osa/pdfs/ratf-final.pdf] Pharmacokinetics describes the way that a compound such as perchlorate moves through the body, including its absorption, distribution, metabolism and excretion. In contrast, pharmacodynamics describes what the compound does in the body, including depressing, stimulating, irritating, or killing cells or systems.

According to the IRIS glossary of terms, a physiologically based pharmacokinetic (PBPK) model estimates the dose of a compound to a target organ or tissue by calculating the rate of absorption in the body, the distribution among target organs, the metabolism of the compound, and the excretion of the compound.[FN41: IRIS Glossary. Physiologically Based Pharmacokinetic (PBPK) Model. http://www.epa.gov/ncea/iris/help_gloss.htm#p] In other words, the PBPK model, by definition and design, estimates the pharmacokinetics of a compound.

The data from EPA's staff report shows that EPA's reliance on a default uncertainty factor of 10 underestimates the variability between fetuses and adults. The Executive Summary of the staff report states that "at a perchlorate dose of 7 ug/kg-day, the percent RAIU inhibition predicted by the model for the near-term fetus is 5-fold greater than the average adult....The same analysis predicts percent RAIU inhibition approximately 1-2 fold higher for the breast- fed and bottle-fed infant (7-60 days) than for the average adult."[FN42: See EPA Staff Paper, Executive Summary, p. 4 and Table 3; see also 73 Fed. Reg. 60278.] More specifically, for perchlorate, the variability between a near-term fetus (40 weeks gestation) and an adult is 5.3-fold. Therefore, the PBPK model supports a pharmacokinetic adjustment factor of at least 5-fold.

The Agency has no information from the PBPK model, or from other data, to develop an intraspecies uncertainty factor for pharmacodynamic variability, particularly between adults and sensitive lifestages. Therefore, EPA should retain a factor of at least 3-fold or more to adjust for pharmacodynamic uncertainty, consistent with its current practice.

To be consistent with EPA policy and practice, EPA should use a total intraspecies uncertainty factor of 15-fold, rather than 10 fold. Based on the data from the PBPK model to support a pharmacokinetic intraspecies variability factor of 5, and the lack of pharmacodynamic data to support a default factor of 3, the use of a 15-fold uncertainty factor is supported by the available data.

Response: EPA agrees that the modeled estimates of alternative HRLs reflect only pharmacokinetics and do not consider uncertainty due to pharmacodynamics. EPA's RfDs typically factor in both, with a standard apportionment of 3.16 for each. EPA does not believe that it is possible to determine whether a 10-fold uncertainty factor is sufficient to reflect both pharmacokinetics and pharmacodynamics. However, EPA acknowledges that 10X may be insufficient. Data do not currently exist to provide an estimate of the pharmacodynamic component of the intraspecies uncertainty factor.

EPA Comment Code: 2420

Comment: 3. EPA requests suggestions for ways to use the PBPK modeling analysis to inform the regulatory determination for perchlorate that are different from those described in this notice or the October 10, 2008 notice.

The PBPK model can provide useful information to characterize the relative sensitivity of this life stage if model parameters are scientifically defensible and selected from comparable points within their parameter distributions, and if nonscientific considerations do not introduce unexplained bias into the selection of parameter values. To be most useful, EPA should use probabilistic methods to characterize the uncertainty and variability around parameter distributions and the range and likelihood associated with model-predicted RAIU inhibition for each population or life stage. Use of probabilistic methods is consistent with the Agency's current recommendations for use of probabilistic methods in risk assessment to help inform risk management decisions.[FN12: http://www.epa.gov/fedrgstr/EPA-RESEARCH/2009/August/Day-18/r19755.htm; http://vvww.epa.gov/raf/prawhitepaper/pdf/pra_mgr_summary_0609.pdf.]

Additional considerations would provide perspective on the significance of the IUI associated with low dose perchlorate exposure. For example, EPA should present the change in RAIU inhibition when the RfD is modeled rather than the Greer et al. (2002) POD, which is ten fold higher.

Response: EPA believes that the modified Clewell (2007) model is useful in examining which life stages are most susceptible to the effects of perchlorate. For example, the model indicates that a fetus may be seven times more sensitive to the effects of perchlorate than a pregnant woman. The model also allows for the estimation of the concentration of perchlorate in breast milk (thus breast-fed infant exposure) at various maternal perchlorate exposure levels. Data do not exist at this time to permit a more expansive development of the model for various life stages.

EPA believes that the RfD derived by the NRC using the Greer et al. (2002) remains the appropriate estimate of health effects due to perchlorate for use in assessment of risk.

Comment: Also, multiple chemical agents affect the uptake of iodide into the thyroid in the same way as perchlorate. These goitrogens, which include thiocyanate and nitrate, can be found naturally in common foods, including produce, milk, and cured meats. Incorporation of thiocyanate and nitrate exposure into the PBPK model should provide useful information on the relative IUI caused by exposure to these agents and to perchlorate. Thus, daily diets for children and adults including these foods are predicted to have a greater effect on IUI than would result from drinking two liters of water containing perchlorate at environmentally relevant levels (e g., estimated perchlorate drinking water equivalent concentrations associated with the thiocyanate and nitrate present in these

diets are estimated to be at least 1,500 to 29,000 ppb). Based on these data, the contribution of perchlorate in drinking water at a concentration of 20 ppb (assuming consumption of 2 liters per day) to total daily IUI associated with a typical diet would be a fraction of these values.

Response: EPA does not disagree that a total iodine inhibitor load, including naturally-occurring NIS inhibitors, should be considered. However, adequate data do not exist at this time to characterize adequately the relative affinity of various iodide uptake inhibitors for the NIS receptor. In addition, no data exist to characterize their relative potency in impacting thyroid hormone levels. Given this lack of data, EPA believes that it is prudent to consider the potential adverse health effects for perchlorate independently until data are developed to permit consideration of multiple goitrogens jointly.

Comment: According to the office of environmental health hazard assessment, see link: http://www.oehha.ca.gov/public_info/facts/faqperchlorate.html, perchlorate has not been scientfically proven to cause cancer in humans at the doses likely to be in drinking water. The University of California conducted 3 separate studies on the topic.

Response: EPA respectfully disagrees with this comment. In 2003, the National Research Council (NRC) of the National Academy of Sciences (NAS) was asked by EPA to assess the current state of the sciences regarding potential adverse effects of perchlorate exposure and to determine whether EPA's prior perchlorate risk assessment findings were consistent with current scientific evidence. In a NRC 2005 review ("Health Implications of Perchlorate Ingestion", (NRC, 2005)), the NRC recommended that data from the Greer et al. (2002) human clinical study be used as the basis for deriving a perchlorate reference dose (RfD) (NRC, 2005). From this Greer et al. (2002) human clinical study, the statistical no observed effect level (NOEL) for the perchlorate-induced inhibition of thyroid iodide uptake was determined to be 7.0 ug/kg, which corresponded to an iodide uptake inhibition of 1.8 %. The NRC concluded that the most health protective and scientifically valid approach to deriving a reference dose for perchlorate was to base the perchlorate RfD on the inhibition of iodide uptake by the thyroid, and that iodide uptake inhibition, though not an adverse effect per se, is the most appropriate precursor event, and would precede any more severe adverse health effects of perchlorate exposure in humans. The NRC recommended basing the RfD on a precursor to an adverse effect rather than an adverse effect, per se. The precursor event precedes a downstream adverse effect in the dose response continuum. In this case, NRC used prevention of iodide uptake inhibition, a precursor to adverse thyroid effects, to establish a level at which no adverse effects would be anticipated in exposed populations. This approach is consistent with the Agency's policy on the use of precursor events when appropriate in establishing the critical effect upon which an RfD is based (U.S. EPA, 2002). The NRC recommended that EPA apply an uncertainty factor of 10 to this NOEL of 7.0 ug/kg for the perchlorate-induced inhibition of thyroid iodide uptake, to account for differences in sensitivity between healthy adults and the most sensitive sub-population, consisting of fetuses of pregnant women who might have hypothyroidism or iodide deficiency. Iodide uptake inhibition has been identified in the literature as an area of concern in connection with increasing the risk of neurodevelopmental impairment in fetuses of high-risk mothers. The NRC viewed the recommended uncertainty factor of 10 as conservative and protective of health, given that the NOEL is based on a non-adverse effect (iodide uptake inhibition) which precedes the adverse effect in a continuum of possible adverse biological effects of perchlorate exposure. NRC recommended that using a non-adverse effect that is upstream of the adverse effect

represents a more conservative, health-protective approach to the risk assessment for perchlorate, noting that the purpose of the 10-fold uncertainty factor is to protect sensitive subpopulations in the face of uncertainty regarding their relative sensitivity to perchlorate exposure. EPA has adopted the NRC's recommendations in its "Integrated Risk Information System" (IRIS) (USEPA 2005), resulting in an RfD of 0.7 ug/kg/day, which was derived by applying a 10-fold (10x) uncertainty factor to the NOEL of 7.0 ug/kg/day. Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of

health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: 1. Perchlorate interferes with the functioning of the thyroid gland which can disrupt metabolism regulation in adults. However, the effects on children can be much worse causing irreversible developmental problems. This is particularly concerning when the U.S. Food and Drug Administration's Total Diet Study:

Dietary Intake of Perchlorate and Iodine study revealed that children two years of age have the highest total perchlorate intake per day and infants have the second highest perchlorate intake per day. 2. The RFD of .07 Âµg/kg translates to a drinking water equivalent of 24.5 ppb, based on 2 liters consumed by an adult daily. However, this assumes that the only source of perchlorate is drinking water. The 2004-2005 Exploratory Survey Data on Perchlorate in Food Samples listed several foods that were found to have perchlorate. One milk sample revealed levels of over 10 ppb Âµg/L. Samples of green beans revealed levels as high as 25.9 ppb. Samples of oranges revealed levels as high as 23.3 ppb. This is alarming as these foods are all essential to growing children who may be more prone to higher levels of perchlorate already. The translated RFD of 0.7 Âµg/kg to 24.5 ppb is calculated for adults. This level may be even lower for children and does not include any

perchlorate intake from food they may consume. Another serious consideration is the seemingly high levels of perchlorate that could be consumed by infants if fed formula mixed with drinking water. For the reasons stated above, I urge EPA to reconsider setting a national maximum contaminant level for perchlorate in drinking water. The states that have already imposed a maximum contaminant level for perchlorate have set the standard much lower than 24.5 ppb, suggesting that those states have concluded that a safe level of perchlorate intake is less than 24.5 ppb.

Respectfully submitted,

Crystal D. Lay

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of

health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: Dear EPA This is a Public Comment Regarding EPA's refusal to regulate Perchlorate under the Safe Water Drinking Act (Docket ID EPA-HQ-OW-2008-0692).

Perchlorate is a chemical in rocket fuel that has been associated with decreased thyroid hormone levels in pregnant women, newborns and young children. Thyroid hormone is critical for growth and development, especially in the brains of fetuses and children. Perchlorate inhibits iodine uptake and the synthesis of thyroid hormone by the thyroid gland. The CDC showed that exposure to perchlorate levels as low as 5 ppb was associated with decreased thyroid hormone levels, especially in women with lower iodine levels. In other words, exposures at levels significantly lower than the level EPA assumes is "safe" i.e., the EPA RfD of 24.5 ppb, were linked to a lowering of thyroid hormone levels that can cause significant adverse health effects in exposed women and fetuses. Since over 16 million Americans are at risk of exposure to elevated levels of perchlorate, extrapolation of this study to the entire US population indicates that approximately 2 million women of childbearing age are at risk from abnormally low thyroid hormone levels.

Adequate levels of thyroid hormone are also critical to normal growth and cognitive development in infants. Infants are likely to be particularly vulnerable to perchlorate since they have rapid turnover of thyroid hormone, as well as, low reserves of thyroid hormone.

Response: EPA acknowledges and thanks you for providing comments. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Comment: NOVEMBER 10 2008

US Environmental Protection Agency Office of Water Docket (Mailcode: 2822T) 1200 Pennsylvania Avenue, NW Washington, DC 20460

RE: Comments on Regulatory Determination on Perchlorate Docket EPA-HQ- OW-2008-0692

Drs. Carol Bigelow, Larry Schwartz, and R. Thomas Zoeller are pleased to submit comments to the US EPA on Docket ID No. EPA-HQ-OW-2008-0692, entitled "Drinking Water: Preliminary Regulatory Determination on Perchlorate". In brief, the authors of docket ID No. EPA-HQ-OW-2008-0692 propose that there be no national primary drinking water regulation, the rationale being that such would not present a "meaningful opportunity for health risk reduction for persons served by public water systems". EPA's proposal not to regulate perchlorate in public water systems:

(1) Lacks the requisite scientific basis. Specifically, EPA regularly cites the nearly 4 year-old NAS report (NRC, 2005) without a critical evaluation of the science underlying the document and how new information should be integrated into it. This issue is most germane in the emphasis on the pregnant woman and fetus as the most sensitive population to perchlorate exposure. EPA fails to consider published, peer-reviewed data demonstrating that the current RfD for perchlorate exposure is not protective of neonates and infants (Ginsberg and Rice, 2005; Ginsberg et al., 2007).

(2) Lacks critical evaluation of the literature employed to justify its decision. Methodologically sound research indicates an association between perchlorate exposure and thyroid function in adult women with low iodine intake (Blount et al., 2006a; Steinmaus et al., 2007). If infants are no more sensitive to perchlorate than adult women, brain damage will occur at the median level of perchlorate exposure, according to published data (reviewed by (Ginsberg et al., 2007)). Thus, the CDC study should reasonably replace the 6 year-old "Greer Study" (Greer et al., 2002) as the point of departure for RfD development.

(3) Fails to critically evaluate the reliability of null findings. EPA justifies ignoring the Blount Study using a series of studies that identify no relationship between perchlorate exposure and thyroid function in humans. However, EPA is apparently unaware of published data describing the variability of serum thyroid hormone measures in adults (Andersen et al., 2002; Andersen et al., 2003) and in neonates (Herbstman et al., 2008a; Herbstman et al., 2008b). It is our opinion that critical analysis of the null findings employed by EPA to justify ignoring the findings in the Blount Study will demonstrate that these null findings cannot be interpreted to indicate no relationship between perchlorate exposure and thyroid function.

(4) Relies on a PBPK model parameterized with weak data. It is discouraging that EPA went to the effort of obtaining the code for the Clewell et al. PBPK model and modified it without critically evaluating the data employed to parameterize the model.

Considering these 4 points, it is our opinion that a scientifically valid RfD and HRL will be significantly lower than that the current proposal. Moreover, the data are available to scientifically defend a return to EPA's draft RfD of 2002.

Response: EPA acknowledges and thanks you for providing comments. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to

regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: Thyroid hormone insufficiency in the neonate and infant leads to irreversible health consequences. Defects in thyroid hormone regulation negatively impact brain development and may contribute to a cluster of irreversible neurological defects that includes autism. This literature - completely ignored by EPA's analysis - is compelling public health rationale for regulating perchlorate exposure.

Perhaps the best examples of infants' unique sensitivity to thyroid hormone insufficiency are the studies of infants with congenital hypothyroidism (CH) (for review, see (Zoeller and Rovet, 2004)). These studies are particularly useful because subjects are under continuous medical surveillance so there is good documentation of the relationship between endogenous thyroid hormone, levels of hormone supplementation, and developmental outcome (Heyerdahl and Oerbeck, 2003). The neuropsychological outcome of children diagnosed with CH at birth is associated with both the severity of CH and early treatment factors (how soon T4 was administered, starting dose and serum T4 levels during the first two years of life). These T4 parameters were highly correlated with verbal IQ at age 20, and children with CH who ultimately completed high school had a significantly higher T4 starting dose than those who did not (Oerbeck et al., 2003). Strikingly, the difference in mean starting dose between these two groups was a modest 2.1 ug/kg-day. Because iodine represents 65% (w/w) of T4, the amount of iodine associated with that T4 difference was only 1.37 ug/kg-day. Independent studies were consistent in their findings. In Selva et al. (2002) and Selva et al (2005), a difference in starting dose of only 12.5 μg/day (8.13 ug/day iodine equivalent or 2.3 ug/kg/d) was associated with a significant difference in full scale IQ of 11 points (Selva et al., 2002; Selva et al., 2005). Thus, small differences in available thyroid hormone (and the iodine associated with it) during the first few weeks of life can have significant lifetime consequences including, especially, reduced IQ.

In addition, the experimental literature clearly demonstrates that specific neurodevelopmental events are irreversibly damaged by marginally-low thyroid hormone. These include neuronal migration (Lavado-Autric et al., 2003; Auso et al., 2004), synaptic function (Gilbert and Sui, 2006, 2008), white matter development (Sharlin et al., 2008), and the development of nodular heterotopias (Goodman and Gilbert, 2007). Each of these developmental events will have cognitive and neurological sequelae in humans.

In its unsupported reliance on the NAS report of 2005 (NRC, 2005), EPA did not focus their analysis on the relevant vulnerable groups, the neonate and infant. In this regard, EPA failed to employ one of the largest, and critically relevant, data sets relating thyroid hormone to health consequences - that of neonates and infants (see (Chan and Rovet, 2003; Zoeller and Rovet, 2004)). The superficial reference EPA makes to the infant is wholly inadequate in the current version of this document and should take into consideration the issues developed above and expanded previously (Ginsberg et al., 2007). In addition, EPA should review the issue of genetic factors that may impact individual sensitivity to perchlorate exposure (Scinicariello et al., 2005). Due consideration to this published literature will dramatically change the EPA's analysis.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: Also lacking in the science presented in docket ID No. EPA-HQ-OW-2008-0692 are the power considerations necessary to inference making that is precise. Indeed, several of the studies relied upon by the US EPA lacked the statistical power needed to rule out a non-null association.

EPA has failed to address key questions regarding the studies it uses to defend ignoring the CDC study. Specifically, given the known variability in measures of thyroid function (Andersen et al., 2002; Andersen et al., 2003) and maternal, infant and delivery factors on neonatal and thyroid status (Herbstman et al., 2008a; Herbstman et al., 2008b), to what extent do epidemiological studies exploring the relationship between perchlorate and thyroid function provide reliable evidence of a null relationship? Andersen et al. (Andersen et al., 2003) discuss the sources of variability in measures of thyroid hormone in adults. These are critical considerations to employ in estimating the ability of epidemiological studies to identify relationships of interest between perchlorate and thyroid function. Moreover, Andersen et al. (2002) found that to identify the homeostatic set-point within 5% precision required 85 individual measures of TSH and 25 of total T4. Given this degree of variation, studies comparing average measures of thyroid function and proxy measures perchlorate exposure have little - if any - ability to identify relationships of interest. Therefore, EPA is required to determine which of the epidemiological studies it used in its analysis had the potential to identify

a relationship between perchlorate exposure and thyroid function, and the degree to which null findings are meaningful.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: Perchlorate interferes with iodine uptake in the thyroid gland, leading to low thyroid production, termed hypothyroidism. Perchlorate also impedes the thyroid's ability to produce hormones that foster mental and physical development. Robert Zoeller, a professer at the University of Massachusetts who specalizes in thyroid hormone and brain development stated a reduction in thyroid function in fetuses, newborns, and children could translate to a loss of IQ and an increase in behavior and perception problems. Zoeller also stated that the impacts are irreversible, meaning that even small changes in thyroid functions in early life have impacts on functioning through high school and even into people's early twenties.

Response: EPA acknowledges and thanks you for providing additional information related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: New data indicate that increases in TSH, resulting from decreased circulating thyroid hormones, may also increase perchlorate uptake in the thyroid (Tran et al. 2008).

There are critical windows in fetal, neonatal, and infant development where insufficient thyroid hormones are associated with disruptions in neural development leading to cognitive deficits (Woodruff et al. 2008). The NIS is expressed in the placenta, and a recent study has shown that the NIS can transport perchlorate across the placental barrier and lead to increased exposure to the developing fetus (Tran et al. 2008). It is therefore not unreasonable to suggest that perchlorate transport could be exacerbated by low maternal thyroid hormones that stimulate TSH release, which enhances perchlorate transport into the maternal thyroid, and across the placental barrier (Tran et al. 2008). Several studies have shown that even moderate maternal thyroid hormone insufficiency during these critical developmental windows can have a significant and lasting impact on the child, such as reduced IQ scores (Haddow et al. 1999; Morreale de Escobar et al. 2000; Pop et al. 2003). Comprehensive studies of the impact of perchlorate exposure on children of mothers that have low iodine intake are lacking, and increased research in this area is needed.

This problem is complicated by extensive individual variability such that the current ranges used to assess thyroid health may not effectively identify adverse downstream effects (Anderson et al. 2002). Therefore, the focus on modulation of thyroid hormones rather than clinical endpoints may be warranted because important concerns have been raised regarding the current method used to assess thyroid health, specifically comparison of thyroid hormone levels with pre-defined acceptable ranges. In their study Anderson et al conclude: "we found that individual reference ranges for serum T3 and T4 are about half the width of population based reference ranges. Hence, a test result within the laboratory reference limits is not necessarily normal for the individual." This is consistent with, and may help explain the observation discussed above, that even small decrements in maternal T4 that do not constitute clinical hypothyroidism can impact neurological development in children. In fact, there is evidence that hypothyroidism is prevalent in the US, yet often undetected, and untreated (Aoki et al. 2007)

An additional complicating factor is that Centers for Disease Control and Prevention (CDC) data indicate that over thirty percent of US women are not obtaining sufficient iodine (Caldwell et al. 2005). Insufficient iodine intake can predispose the thyroid gland to adverse effects of endocrine disrupters especially under phases of vulnerability during development and under adaptive challenges during diseases (Kohrle 2008). Thus, insufficient iodine intake could increase vulnerability to perchlorate. Insufficient iodine intake, assessed by comparing urinary iodine excretion to World Health Organization standards for iodine sufficiency, can increase sensitivity to uptake inhibition by perchlorate.

These major factors described above and summarized below present a clear case that perchlorate exposure poses a significant health risk in the US:

* The principle mode of action of perchlorate is inhibition of iodide uptake by the thyroid, * More than thirty percent of US women are not getting sufficient iodine, * Hypothyroidism is prevalent in

the US population, yet often undetected and untreated, * Neurological damage can occur in babies born to with subclinical hypothyroidism.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: 2. EPA is ignoring data that demonstrates setting an MCL for perchlorate will provide a meaningful opportunity for health risk reduction

A. Data since the NRC report suggest that perchlorate is even more hazardous than previously thought.

Even based on older studies, EPA acknowledged in its preliminary determination that perchlorate may have adverse health effects. More recent studies show that the effects on humans may be even more dangerous than EPA thought.

Data showing that perchlorate is actively transported into mammary epithelial cells by the sodium iodide symporter (NIS), resulting in an accumulation of perchlorate in breast milk[FN23: Dohan, O, C Portulano, C. Basquin, A Reyna- Noyra, LM Amzel, and N Carrasco. 2007. The Na+/I-symporter (NIS) mediates electroneutral active transport of the environmental pollutant perchlorate. PNAS 104(51):20250-20255.][FN24: Dasgupta, P. K., Kirk, A. B., Dyke, J. V., and Ohira, S.-I. (2008). Intake of Iodine and Perchlorate and Excretion in Human Milk. Environ. Sci. Technol. 42, 8115-8121. Docket HQ-OW-2008-0692 NRDC comments on perchlorate HRL] suggests that perchlorate may not only inhibit iodide accumulation in maternal milk but also could be transferred through milk to the nursing infant where it would be predicted to inhibit iodide uptake in the infant's thyroid gland. The NIS also is found in the placenta and based on this new research, it seems likely that perchlorate is actively transported across the placenta. Because the fetus and developing infant require adequate iodide for thyroid hormone function, any determination of a safe level of exposure to perchlorate should take into account this mode of action for perchlorate toxicity.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: C. Sensitive populations not protected by HRL

A related study estimates perchlorate doses that correspond to urinary perchlorate excretion (hereinafter referred to as "Blount (2007)").[FN62: Blount BC, Valentin-Blasini L, Osterloh JD, Mauldin JP, Pirkle JL. Perchlorate exposure of the US Population, 2001-2002. J Expo Sci Environ Epidemiol. 2007 Jul;17(4):400-7. Epub 2006 Oct 18.] These calculations are feasible because perchlorate is not metabolized and has a short half-life of approximately 8 hours[FN63: Ibid.]. Blount (2007) showed that the adjusted geometric mean for perchlorate exposure in women was 0.059 ug/kg-day, and the 95th percentile exposure was 0.215 ug/kg-day. This means that the adverse effects described by Blount (2007) are occurring at perchlorate exposures below the RfD of 0.7 ug/kg- day, with the logical inference being that the proposed HRL will not protect sensitive subpopulations.

A study by Ginsburg et al.[FN64: GL Ginsburg, DB Hattis, RT Zoeller, and DC Rice. 2007. Evaluation of the U.S. EPA/OSWER preliminary remediation goal for perchlorate in groundwater: Focus on exposure to nursing infants. Environ Health Perspect. 115(3):361-369. http://www.ehponline.org/members/2006/9533/9533.html] published since the NRC review found that, "drinking-water perchlorate must be < 6.9 ug/L to keep the median, and < 1.3 ug/L to keep the 90thpercentile nursing infant exposure below the RfD."[FN65: GL Ginsburg, DB Hattis, RT Zoeller, and DC Rice. 2007. Evaluation of the U.S. EPA/OSWER preliminary remediation goal for perchlorate in groundwater: Focus on exposure to nursing infants. Environ Health Perspect. 115(3):361-369.] Based on both exposure and toxicity information, and data on sensitive populations, the proposed HRL, which is twice as high as the limit proposed by Ginsberg et al, will leave significant portions of the population at risk.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary

determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: This year, the ATSDR released its Toxicological Profile for Perchlorates (2008) as new data have become available since the last profile of perchlorates in 2005. As a part of their review, ATSDR derives minimum risk levels (MRLs) using available peer reviewed information. MRLs "...are derived when reliable and sufficient data exist to identify the target organ(s) of effect or the most sensitive health effect(s) for a specific duration for a given route of exposure. An MRL is an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer health effects over a specified duration of exposure. MRLs are based on noncancer health effects only and are not based on a consideration of cancer effects. These substance-specific estimates, which are intended to serve as screening levels, are used by ATSDR health assessors to identify contaminants and potential health effects that may be of concern at hazardous waste sites. It is important to note that MRLs are not intended to define clean-up or action levels" (ATSDR, 2008). Considering the NRC report along with new studies published since the NRC report, "ATSDR has adopted the EPA's chronic RfD recommended by the NRC (2005) for the chronic MRL" (ATSDR, 2008).

ATSDR based their MRL on the same most sensitive population, pregnant women and their fetuses, although they also discussed other sensitive populations, preterm and nursing infants. They also state that their decision "...was made after a careful evaluation of the NRC report and of studies that have been published after the NRC (2005) report. The results from newer studies do not change the bottom-line recommendation" (ATSDR, 2008).

The ATSDR Toxicological Profile for Perchlorates was peer reviewed and made available for public comments. "The expert peer reviewers on April 18, 2007 concluded that the MRL should still be based on the RfD as recommended by the NRC Panel Report (2005) given the research data available at the time of the 2007 peer review" (ATSDR, 2008).

Based on the traditional and foundational approach used in science, the weight of evidence-or the number of well conducted studies in humans and animals with appropriate dose-response information-supports EPA's decision not to establish a NPDWR. As shown in the assessment by the NRC in 2005 and the subsequent literature published since then, including the ATSDR Toxicological Profile, the weight of evidence shows that,

* inhibition of iodide uptake in the thyroid gland is a key biochemical event, * the inhibition of iodide uptake is not an adverse effect, * there are doses of perchlorate below which inhibit iodide uptake in healthy adults, * the dose of perchlorate that might be sufficient to cause an adverse effect is as sustained exposure greater than 0.4 mg/kg-d (NRC, 2005), and * there are natural occurring agents, such as thiocyanate and nitrate, that also effect iodide uptake in the thyroid gland.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: The weight of evidence shows that the fetal brain is more sensitive to hypothyroidism than the neonate or infant brain (Boelaert and Franklyn, 2005). Breast milk concentrations of perchlorate have been measured at levels greater than the HRL (Kirk et al., 2005; Pearce et al., 2007b). However, the RfD assumes that if a person consumes 15 ppb of perchlorate not just once, but every day for a lifetime, they will be consuming a concentration of perchlorate that is not anticipated to cause an adverse effect. Furthrermore, a HRL, MRL, PHG[FN1: A Public Health Goal, or PHG, is the State of California's acceptable level of a chemical in drinking water that is not expected to cause an adverse effect if consumed every day for a lifetime.], RfD, etc. are not bright lines above which health effects would be expected to occur. As noted with perchlorate, an RfD based on a no effect level for a non adverse effect in humans with an additional 10-fold uncertainty ("safety") factor provides a health protective approach. The development of a value lower than the RfD will only increase the level of caution. Therefore, if an infant consumes one dose of perchlorate that is greater than the RfD, it is not expected to be any more harmful than a lesser dose. Lastly, a solely breast fed infant will not have exposures through other media.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in

drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: II. KEY SCIENTIFIC STUDIES PUBLISHED SINCE 2005

Since the publication of the NRC report in 2005, several studies have been published that support the conservative nature of the current EPA RfD. Overall, these studies demonstrate that perchlorate is a ubiquitous chemical in the environment, food, and the human body. In a recent study by Blount et al. (2007), all samples of urine measured had low, but detectable concentrations of perchlorate. The sources of perchlorate appear to be both natural and anthropogenic. There is an increasing body of literature demonstrating that much of the environmental perchlorate may be natural or due to non-point sources (DasGupta et al., 2005; SERDP, 2005; DasGupta et al., 2006; Rajagopalan et al., 2006).

[Text Box: The weight-of-evidence of human and animal studies that include sufficient dose-response data, show that possible adverse health effects are several orders of magnitudes above environmentally-relevant levels of perchlorate and that the current RfD is a conservative toxicity guideline value such that contaminants present in drinking water at or below the HRL of 15 ppb would pose no significant health risk to the most sensitive individuals who consume the water on a daily basis over a lifetime.]

Despite the widespread low levels of perchlorate in the environment, studies have not demonstrated an adverse effect due to perchlorate exposure. The NRC report states,

"The committee emphasizes that inhibition of iodide uptake by the thyroid has been the only consistently documented effect of perchlorate exposure in humans. The continuum of possible effects of iodide-uptake inhibition caused by perchlorate exposure is only proposed and has not been demonstrated in humans exposed to perchlorate (with the exception that in patients with hyperthyroidism doses of 200 mg daily or higher may reduce thyroid secretion). More important, the outcomes at the end of the continuum are not inevitable consequences of perchlorate exposure." (NRC, 2005)[FN2: The noted dose of 200 mg/d is a conservative therapeutic value. When use of perchlorate to treat hyperthyroidism was common, doses of 400 mg/d were commonly prescribed, but were found to be slow to control thyrotoxicity and doses needed to be repeated 4 to 5 times/d, due to the rapid excretion of the drug. Although it still took an average of 9.4 weeks, doses of up to 2000 mg/d were given to reduce hyperthyroidism to a remission state (Wolff, 1998).]

The new studies contribute to an already well developed database, adding more studies that are consistent with previous analyses. Furthermore, additional studies that are consistent with the literature also reduces uncertainty (reducing "what we do not know"), thereby reinforcing that the current RfD for perchlorate is both conservative and health protective. Thus, perchlorate concentrations equal to or above the EPA-recommended HRL of 15 ppb in water would also be conservative and health protective for sensitive populations.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: A. Environmental Studies

EPA states: "If adequate human studies (confirmed for validity and applicability) exist, these studies are given first priority in the dose- response assessment, and animal toxicity studies are used as supportive evidence." and "If adequate human data are available, this information is used as the basis of the RfD (EPA, 1989). The scientific studies regarding perchlorate and health are predominately based upon human data, with a range of parameters and dose-response data. The types of human studies are clinical, occupational, or ecological. To date, there is only one epidemiological study which measures perchlorate exposures and outcomes in pregnant women and neonates (Tellez et al., 2005). In contrast to ecological studies measuring collective exposures and outcomes, an epidemiological study measures individual exposure and outcome. There are also some well designed animal studies that have contributed to the health effects database. Many of these studies investigate the relationship between perchlorate exposure and adverse outcomes among especially vulnerable groups. In addition to the clinical studies reviewed by NRC, epidemiological studies are valuable in exploring the health effects due to perchlorate in a chronically exposed genetically-diverse population that includes the population of concern (pregnant women and their fetuses).

In the EPA notice, several of these association studies were taken together, leading EPA to conclude that the results of "...studies of the effects of perchlorate exposure on hormone levels have been mixed" (p. 60266), citing Amitai et al. (2007) showing no effects and Blount et al. (2006) identifying

hormonal changes (although none were outside normal ranges). However, when the strength of the study design is taken into consideration, the weight-of-evidence demonstrates that the current RfD is a conservative toxicity guideline value such that contaminants present in drinking water at or below the HRL of 15 ppb would pose no significant health risk to the most sensitive individuals who consume the water on a daily basis over a lifetime.

Response: EPA acknowledges and thanks you for providing additional information related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: In a peer-reviewed letter to the editor of Thyroid, Gibbs and Van Landingham (2008) reviewed data from their previously published study (Tellez et al., 2005), and showed that in a cohort of pregnant women in Chile, the data do not support the association between environmental perchlorate exposure and changes in thyroid hormones and are consistent with the recent negative findings by both Pearce et al. (2007b) and Lamm et al. (2008), both presented at the Seattle SOT meeting.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. Comment: B. Occupational or Clinical Studies

i. Braverman et al. (2005)

This study included 29 workers exposed for at least 1.7 years in an ammonium perchlorate plant and 12 unexposed volunteers; variables measured in the study included serum perchlorate, thiocyanate, nitrate, total T4, Free T4, total T3, Tg, and TSH; RAIU; and urinary iodine and perchlorate taken after 3 days off or 3 days working. The authors estimated that "half of the workers experienced average ClO4- doses in excess of 0.33 mg/kg-shift over the year preceding this study." They found that there was a decrease in RAIU, but no change in thyroid hormones compared to unexposed controls. There was a slight increase in T3, T4, and free T4 after 3 days working compared to 3 days off. Again, the NRC committee has stated that "The committee does not think that transient changes in serum thyroid hormone or TSH concentrations are necessarily adverse effects" (NRC, 2005). The RAIU dose response curve the authors found was consistent with that of Greer et al. (2002).

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. Comment: ii. Braverman et al. (2006)

In an effort to study the thyroidal effects of a prolonged (six months) exposure to low perchlorate levels in humans, Braverman et al. exposed 13 healthy volunteers to 0, 0.5, or 3.0 mg/d of potassium perchlorate and measured urinary perchlorate levels, radioactive iodine uptake and serum T3, free T4, TSH and Tg concentrations. The 0.5 and 3.0 mg/d doses are equivalent to 250 and 1500 ppb, respectively, assuming a daily water ingestion of 2 liters. The authors concluded that perchlorate at

doses of up to 3 mg/day for six months "...had no effect on thyroid function, including inhibition of thyroid iodide uptake as well as serum levels of thyroid hormones, TSH and Tg" and, "...there was no significant change in the thyroid RAIU during perchlorate administration." (emphasis added)

This study was similar to Greer et al. (2002), but for longer exposures. The doses were 0.5 and 3.0 mg/d and the exposures were for six months. This study also did not restrict or control for dietary intake (Crawford-Brown et al., 2006).[FN6: "If one assumes that the individuals in the study by Greer et al. (2002) were exposed to the same background levels of perchlorate as the rest of the U.S. population (there is nothing in their diets or in the study design to preclude this), then no further RSC adjustment is needed to reflect total exposures via all routes because the risk coefficient from the study already reflects the incremental risk from ingestion of perchlorate in water above and beyond the contributions to perchlorate exposure via the other routes" (Crawford-Brown et al., 2006).] Therefore, the doses administered as part of this study were in addition to the background levels of perchlorate ingested-the impact of dietary iodine intake was not accounted for. The study would have benefited from a larger sample size; however, data from the 14-day Lawrence et al. (2000, 2001) studies, and the Greer Study support the results reported by Braverman et al. These studies all support the NOEL determined by Greer et al. (2002), and relied upon by the NRC as the basis for its recommended RfD.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: Larry Ladd says regulate. Data gap 1: Chronic effects of ClO4- in the skin. Half-life is longer than in the thyroid or the blood (Yu et al 2002, pubmed id 12140178). No discussion of how ClO4- causes drug-induced lupus and erythema nodosum (Beickert & Heinicke 1968, pmed id 4181403), the role I- sometimes plays in relieving erythema nodosum (Boyd 2007, pmed id 17618179; Sterling & Heymann 2000, pmed id 11004629), or similar ailments caused by chaotropic anions such as iododerma, bromoderma, and bromism. Data gap 2: Variation in infant renal excretion of ClO4-. If pendrin is important in ClO4- as well as I- excretion (for I- see Kim et al -- pmed id 19605545) , expect infant with acidosis (including low HCO3- from chronic diarrhea?) to retain more ClO4- (Frische et al 2003, pmed id 12556366). Data gap 3: Chaotropic effects

preventing immuno- coagulation such as opsonization of B-19 parvovirus by IgG (Chehadeh et al 2009, pmed id 19450862, with the parvovirus outbreaks in Dharan after Patriot missile deployment, Mallouh & Qudah 1995 pmed 7715986 [corrected per commenter's request, see docket ID 08090372] and western Pennsylvania during peak fireworks production, Beigi 2008, pmed id 18464909 in mind); opsonization of staph by pentraxin 3, which is dependent on a cysteine array (Holland et al, 2009 pmed id 19054079; Inforzato et al 2008, pmed id 18223257); defensin adhesion to coccidoidomycosis, H. pylori, mycobacteria, and influenza, which is also dependent on a cysteine array vulnerable to changes in salinity (Chandrababu et al 2009, pmed 19480463). Analysis is lacking of NIS and SCN- in the airway (Fragoso et al 2004 pmed id 15345749; Pedemonte et al 2007 pmed id 17404297; Wang et al 2006 pmed id 17142773) and nitrosation in the gastrointestinal tract (Suzuki et al 2003 pmed id 12940440). In regards to humoral immunity, you need to evaluate the thickening of rat pup corpus callosum recorded in York et al 2005 (pmed id 16393938) with the migration paths of cd34+ stem cells within the rat brain (Jendelova et al 2005 pmed id 15929552).

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: Is there an adverse neurodevelopmental effect with perchlorate exposure in an iodine-sufficient population?

Are moderate perchlorate exposures associated with adverse neurodevelopmental or cognitive outcomes? The ecological study Chang et al. (2003) showed there was no increase in ADHD or autism or decrease in fourth-grade performance with perchlorate levels up to 24 ug/L in Nevada. This study was done in the US iodine-sufficient population without distinguishing those with low iodine levels. The Lamm and Dohmland (1999) study found no increased incidence rate of congenital hypothyroidism in California and Nevada counties with perchlorate drinking water levels in the range of 4-16 ug/L.

Are moderate perchlorate exposures associated with lower levels of neonatal thyroxine (or elevated neonatal TSH)? Li et al. (2000a) and Li et al. (2000b) showed no effect on neonatal thyroxine levels

or neonatal TSH levels, respectively, from environmental exposures to perchlorate that ranged up to 15 ug/L, also in Nevada.

At background levels of perchlorate exposure, are lower levels of neonatal thyroxine in the physiological range associated with adverse neurodevelopment outcome including cognition? Soldin et al. (2002) and Soldin et al. (2003) showed in case-control studies that neither childhood ADHD nor pediatric neurobehavioral diseases, respectively, were impacted by variations in neonatal thyryroxine levels. These studies were conducted in Washington, DC, whose water supply has no known perchlorate contamination. Recently, Oken et al. (2009) have demonstrated from a prospective cohort study of 500 children in Massachusetts that cognitive test scores at ages 6 month and 3 years were not associated with lower neonatal thyroxine levels. Further, newborn thyroxine levels were not associated with maternal measures of thyroid function (thyroxine, TSH or thyroperoxidase antibody levels).

Are background perchlorate exposures associated with adverse maternal thyroid function measures? Pearce et al. (2007) presented results demonstrating that maternal thyroid function is not affected by environmental perchlorate exposure, based on urinary perchlorate levels of first trimester pregnant women in Cardiff, UK, where the population is mildly iodine-deficient (i.e, median = 90 ug/L). Pearce et al. (2008) expanded the study in Turin, Italy, asking the same question for an iodine-deficient population.

Pearce et al. (2008) showed among 526 first trimester pregnant women in Turin, Italy, an iodinedeficient population with a median urinary iodine value of 50 ug/L, that there was no association between urinary perchlorate levels and free T4 levels ($r2<0.0001$, $p = 0.9$) or serum TSH ($r2=0.002$, $p = 03$). Their results were the same when they limited their analysis to the 433 women with urinary iodine values less than 100 ug/L. They concluded that "These results, from the largest sample to date of women with low urinary iodine values, do not support the findings reported in the U.S. that similar levels of perchlorate exposure increase serum TSH and lower serum T4 in women with urine iodine concentrations < 100 ug/L."

The Pearce et al. (2008) study is a direct test of the hypothesis raised by the Blount et al. (2006) study, and, in particular for the population of great interest, pregnant women. This study is currently undergoing peer-review for the medical literature.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

EPA Comment ID: 28488
EPA Comment Code: 2500

Comment: In summary, the published studies demonstrate no adverse effect on infant thyroidal or neurodevelopmental health from perchlorate exposures up to 16-24 ug/L and no effect on neurodevelopmental or cognitive health with variations in normal neonatal thyroxine levels. Maternal thyroidal function has not been affected by background perchlorate levels either among UK women in a mildly iodine-deficient population or among Italian women in an iodine-deficient population, even those Italian women with urinary iodine levels less than 100 ug/L. These results challenge the interpretation of the Blount et al. (2006) analyses of the NHANES 2001-2002 cross-sectional database.

These comments are respectively submitted. I would be happy to supply any reference material that is not already in the record, and I keep myself open to participate in any further scientific discussions on these matters.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: Blount et al. and Steinmaus et al. adopted the 100 ug/L level for their studies because it is the WHO/UNICEF/ICIDD criterion for iodine sufficiency (16). However, that level has been recommended as a benchmark for evaluating the median spot urinary iodine level of populations; it has not been advocated for determining iodine sufficiency in individuals. It is not a useful benchmark for individuals because, as described below, individuals demonstrate significant variability of urinary iodine. Many individuals with sufficient iodine intake have spot urine levels <100 ug/L level from time to time.

Urinary iodine levels generally reflect dietary iodine intake over the prior 12-24 hour period, with peaks occurring about 8-12 hours after major meals, thus variations in day-to-day diet can lead to marked day-to-day variations in spot urine iodine (17). Significant day-to-day variations have also been documented in subjects with controlled dietary iodine intake.

For example, six adults studied for 30 days at the NIH Clinical Center were given a diet that provided a constant daily iodine intake (18). Following a six- day stabilization period, daily 24-hour urine specimens were collected for iodine measurements. Day-to-day coefficients of variation (CV) for 24-hour iodine excretion were calculated for each of two successive 12-day periods. Among individual subjects, CVs ranged from 7%-24.1%. Thus, even under controlled conditions, constant diet and 24-hour urine collection, there was substantial day-to-day variability of iodine excretion.

Greater variability was seen in studies that did not restrict subjects' diets and iodine intake.

Rasmussen et al. measured iodine levels in 24-hour urine samples collected on four consecutive days from each of ten subjects whose diets and iodine intake were not controlled. For individuals, day-to-day urinary iodine levels varied up to three-fold (19).

Burgi et al. collected morning urine samples from eleven subjects on 21 consecutive days. Diets and iodine intake were not controlled. For individuals, day-to-day CVs ranged from 15%-75%; the average day-to-day CV for the group was 39%. Results from individual subjects demonstrated hectic day-to-day variability (20).

Andersen et al. measured urinary iodine in 15 men sampled monthly for 12 months. Diets and iodine intake were not controlled. Twelve-month averaged urine levels for individuals ranged from 29-81 mg/L, but individual monthly urine levels ranged from 10-260 mg/L. The CVs calculated for each subject's 12 monthly samples ranged from 20.1%-70.5 % (21).

In addition, urinary iodine excretion follows diurnal and seasonal cycles. Higher urine iodine levels are generally found in morning samples and wintertime samples (17).

Because of such day-to-day variations in urine iodine excretion, studies that consider only isolated spot urine levels report significantly greater dispersion of individual urine levels than do studies which average urine levels over time. In other words, isolated spot urinary iodine levels are imprecise reflections of an individual's iodine sufficiency.

More generally, isolated urinary iodine levels provide little useful information about the long-term iodine nutrition of an individual. For example, consider the views of the National Academy of Clinical Biochemists (17):

"In most circumstances the determination of urine iodine provides little useful information on the long-term iodine status of an individual, since the results obtained merely reflect recent dietary iodine uptake."

For such reasons, dividing a population into two groups solely on the basis of a single spot urinary iodine level, as in the Blount and Steinmaus studies, will almost certainly lead to significant exposure misclassification. Blount et al. and Steinmaus et al. recognized that possibility, but argued that such misclassification would be "random error (not bias)" and thus "nondifferential and therefore likely to bias estimates of association toward the null, not toward the positive effects" (14). That statistical argument is valid for nondifferential misclassification of binary exposure categories, but it is not necessarily valid for more complex sorts of misclassifications:

"Contrary to popular misconceptions, however, nondifferential exposure or disease misclassification can sometimes produce bias away from the null." (22)

The Blount et al. study classified individuals based on single spot urine levels of iodine and perchlorate; Steinmaus et al. also included a spot urine level for thiocyanate. Misclassifications would not have been simple and binary. Still greater complexity and potential bias arise from the fact that day-to-day variations of iodine and perchlorate intake do not vary randomly from each other. For example, the FDA Total Diet Study (23) documents that some food groups (e.g., dairy) are major sources of both iodine and perchlorate, while others (e.g., grains, vegetables) are rich in only one or the other. Thus, day- to-day dietary variations may result in either strongly positive or strongly negative associations between these two anions. In any event, their relationship is unlikely to be random. Further complicating analytical assessment and interpretations is the fact that iodine and perchlorate have different serum half-lives and different urinary excretion rates (11,12).

It is not reasonable to minimize the importance of such misclassification by reliance on "popular misconceptions". Even more complex misclassification bias and confounding can be expected when other 'NIS stressors' (e.g., thiocyanate and nitrate) are measured in isolated spot urines and included in the analysis. For such reasons, cross-sectional data based on isolated spot urine samples must be used with caution when inferring causation and estimating the magnitude of potential interactions.

For the same reasons, isolated spot urine levels should not be used to characterize the proportion of a population deemed "iodine deficient"; doing so will overestimate the number of "deficient" individuals. That concern was also expressed by the NAS Committee to Assess the Health Implications of Perchlorate Ingestion ("NAS Committee") (24):

"... the distribution of iodide values measured in spot urine samples is broader than values measured repeatedly in individual subjects (21); this leads to overestimation of the number of subjects with both low and high values."

The NAS Committee also raised concerns about the over-interpretation of NHANES spot urine iodine data to suggest that significant numbers of young adults (including pregnant women) had significant iodine deficiency because their spot urine levels were <100 ug/L (24)

"Furthermore, among people 15-44 years old, including pregnant women, there were no differences in serum TSH and T4 concentrations between those with urinary iodide values less than 50 ug/L and those with higher values (25); apparently, the iodide intake in the former group was not low enough to cause a fall in T4 secretion."

In reviewing these concerns, the OIG concluded that there was "significant uncertainty" when NHANES data for isolated spot urinary iodine were used as the basis for determining iodine sufficiency in pregnant women:

"these results do represent a significant uncertainty in the science concerning this public health issue (i.e., what portion of the U.S. pregnant women population are moderately or mildly iodide deficient?)." (13)

In summary, use of simultaneous measurements of iodine, perchlorate and other NIS stressors in isolated spot urine samples to characterize cross-sectional populations can be expected to result in significant misclassification that may bias associations toward or away from the null. Likewise, they are likely to overestimate the numbers of individuals at the extremes of the population distribution. Analytical findings and population characterizations based on such testing are likely to introduce significant uncertainty in regulatory determinations that rely upon them.

Thank you for this opportunity to comment upon and contribute to your regulatory determination for perchlorate.

Yours truly, Jonathan Borak, MD, DABT, FACP, FACOEM Clinical Professor of Epidemiology and Medicine Yale School of Medicine

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Section IV. Consideration of Studies Published Since EPA Adopted the NAS RfD for Perchlorate

Page & Paragraph Page 41891

Comment We would like to call to EPA's attention the new data from the Cao, et al. 2009 perchlorate, thiocyanate, and nitrate manuscript developed in collaboration with the CDC, which the authors believe is the first study of its kind. Individual thyroid function and perchlorate, thiocyanate, and nitrate exposure were directly measured in about 50 infants born at the Children's Hospital of Philadelphia, the Hospital of the University of Pennsylvania, and affiliated clinics, in a study conducted in 2004-2005 where ninety-two full term infants between birth and 1 year of age participated.

In general, the authors' draft manuscript states that associations between TSH and thiocyanate were larger than those between TSH and perchlorate and nitrate. Also, a mixed linear model (one goitrogen exposure at a time) showed that the three goitrogens all had significantly positive associations with TSH and T4. The average urinary thiocyanate level in these infants was almost 50 times higher than average perchlorate level, and thiocyanate was more strongly related to TSH than perchlorate. With all three [goitrogens] modeled simultaneously, all children with higher nitrate and thiocyanate had higher TSH, but higher perchlorate was significant only in children with low iodide.

Suggested Action, Revision and References (if necessary) As EPA continues to evaluate new perchlorate data as stated in the FR announcement this study should be a relevant consideration.

Section IV. Consideration of Studies Published Since EPA Adopted the NAS RfD for Perchlorate

Page & Paragraph Page 41891

Comment The recent publication describing a model by M. Lorber entitled, "Use of a simple pharmacokinetic model to characterize exposure to perchlorate," Journal of Exposure Science and Environmental Epidemiology (2009) 19, 260-273 was not cited by EPA when evaluating perchlorate modeling alternatives. According to the author:

The primary benefit of these simple models is that they allow for an expanded study of the magnitude and patterns of external exposure. This is a different emphasis than the complex, PBPK models, which are used more to study the internal fate (e.g., dose-to-target organs) and potential health effects of contaminants to which an individual is exposed. ...In short, these simple models are allowing for an expanded and more valid study of external patterns of exposure.

Suggested Action, Revision and References (if necessary) The EPA "in-house" model developed by M. Lorber should be given consideration as appropriate.

Section V. Next Steps

Page & Paragraph Page 41892

Comment Although EPA indicates that no additional research is needed to make a regulatory decision, Blount et al. (2009), the USEPA OIG perchlorate document (December, 2008), and others have stated that perchlorate, thiocyanate and nitrate from dietary exposure, coupled with low iodine intake merits further research.

Suggested Action, Revision and References (if necessary) We do not want to delay the regulatory process, but encourage further research in these areas to decrease uncertainty associated with perchlorate cumulative risk assessment.

Comment: 2) MORE RECENT STUDIES

Subsequent to the NAS report, Braverman et al 2005 demonstrated the same dose response as Greer for iodine uptake inhibition, among workers with long term perchlorate exposure. There were no demonstrable adverse thyroid effects among the workers in this study or in a previous study at the same location (Lamm et al 1999). Benchmark calculations (Crump & Gibbs 2005) were performed on the data from these two studies as well as with data from the Greer study. The lower 95% statistical confidence limits on benchmark doses estimated from a combined analysis of the two occupational studies ranged from 0.21 to 0.56 mg/kg-day for free T4 index and from 0.36 to 0.92 mg/kg-day for TSH. Corresponding estimates from the short-term clinical study were within these ranges.

Tellez et al 2005 conducted an epidemiological study among pregnant women in Chile and found no impact of perchlorate on maternal thyroid function during pregnancy or on infants at birth. Water perchlorate concentrations ranged from 4ppb to over 100 ppb. Amitai et al 2007 studied neonatal T4 in a region of Israel where perchlorate contamination was found in the public water supply at concentrations far in excess of those documented in the U.S. This study finds no change in neonatal T(4) levels despite maternal consumption of drinking water that contains perchlorate at levels in excess of the Environmental Protection Agency (EPA) drinking water equivalent level (24.5 microg/L). Therefore the perchlorate RfD is likely to be protective of thyroid function in neonates of mothers with adequate iodide intake.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: Again, we certainly appreciate the need for modeling when sufficient empirical data do not exist. However, in the case of perchlorate, significant peer- reviewed literature is available that should be considered by EPA before relying on less certain modeling to generate HRLs. **Response:** EPA acknowledges and thanks you for providing comments. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: Subject: Docket ID No. EPA-HQ-OW-0297

Reference: Drinking Water: Perchlorate Supplemental Request for Comments (Federal Register / Vol. 74, No. 159 / Wednesday, August 19, 2009 / Notices

The Nevada Division of Environmental Protection (NDEP) provides herein, comments to assist the US Environmental Protection Agency (EPA) in their evaluation of the benefits of establishing a national primary drinking water rule for perchlorate. The EPA is evaluating whether establishing this rule would provide a significant reduction in human health risk by reducing exposure to perchlorate in drinking water. In that context, NDEP comments are provided in response to an August 19, 2009 notice within the Federal Register entitled "Drinking Water: Perchlorate Supplemental Request for Comments", Docket ID No. EPA-HQ- OW-2009-0297.

Comments are arranged in the order presented within the above-referenced Federal Register Notice (Notice). The numerical designation follows that used in the Notice. The attached appendices provide supporting information, along with a reference to guide the reader to specific supporting information. These references provide examples, describe assumptions, and enhance the clarity of the comments. Applicable references are cited throughout the text and appendices, and are listed at the end of this document.

III. Alternative Approaches to Analyzing Scientific Data Related to Perchlorate in Drinking Water:

A. Interpretation of the Physiologically-Based Pharmacokinetic (PBPK) Modeling 4. Request for Comment on Alternative Approaches a. EPA requests comment on using the PBPK model to evaluate the relative sensitivity of various life stages to perchlorate exposure in drinking water.

Comment A.4.a.1: It is inappropriate to use the PBPK model to support a regulatory action because the underlying scientific evidence indicating sensitivity of the fetus and/or neonate is lacking. Additional clinical data are needed to help refine the PBPK model. Data are needed for adults, including pregnant women, and for neonates concerning thyroidal iodine capacity and the effects of sodium-iodide symporter (NIS) upregulation on thyroidal iodine uptake and/or thyroxine levels. Also, additional studies of other adults are needed to evaluate the effects of temporary iodine deficiency and NIS upregulation on perchlorate competitive inhibition of thyroidal iodine uptake and/or free thyroid hormone levels. This additional research would provide useful data to consider in further refining the PBPK model to accurately reflect the effects of iodine deficiency in pregnant women, fetuses and neonates. If the additional clinical data support concerns for relative sensitivity of the fetus and neonate, then a refined and validated PBPK model would be useful.

Comment A.4.a.2: Perchlorate is known to be well absorbed into the human body, and at sufficient doses can act as an inhibitor of iodine uptake into the thyroid due to competition with iodine for the sodium-iodide symporter (NIS) (NRC, 2005). Although this competitive inhibition of NIS is not an adverse health effect, it is apparently the first step in a cascade of events that ultimately reduces the production or release of thyroxine from the thyroid gland into the bloodstream by depleting stored

iodine in the thyroid. However, humans have multiple and redundant mechanisms for maintaining adequate amounts of free thyroid hormones (free thyroxine (FT4) and the active hormone receptor-binding agent, free tri-iodothyronine (FT3)) when diet or environmental agents cause interruption of thyroidal iodine intake or in circulating active hormone levels (Moore, 1984; Moulopoulis et al., 1988). Some of the most prominent homeostatic mechanisms for maintaining adequate levels of circulating FT3 in humans include:

1. NIS upregulation capacity to rapidly (within hours) increase thyroidal iodine uptake; 2. Organification of iodide within the thyroid into thyroglobulin, a protein containing bound T4 subunits that act as a storage pool within the thyroid; 3. Thyroid stimulating hormone (TSH) secretion and thyrotropin releasing hormone (TRH) secretion triggered by various stressors (e.g., cold or fever) or by lowered FT3 in circulation, leading to increased production and secretion of T4 and T3 into the bloodstream; 4. Hypertrophy and/or increase number and volume of thyroid follicular cells (including induction of goiter) with long-sustained TSH stimulation typically from FT3 shortage in circulation; 5. Modulation of thyroid binding globulin (TBG) content in the circulation which alters the storage capacity and free vs. bound hormone balance in the circulation; 6. Modulation of iodide and thyroid hormone excretion via the kidneys, feces, and/or metabolic breakdown of hormones; and 7. Modulation of thyroid function and thyroid hormone distribution by estrogens, human chorionic gonadotropin, leutinizing hormone, and other hormones during pregnancy and lactation.

The human body is recognized to maintain a sensitive and dynamic balance between TSH and FT3, and the thyroid injuries or diseases that significantly alter this dynamic balance (in magnitude and/or duration) have the most clinical importance with respect to thyrotoxicity and adverse health consequences (Moore, 1984; Moulopoulis et al., 1988).

The homeostatic mechanism perhaps most relevant to perchlorate thyrotoxicity in humans and other mammals is the upregulation of NIS when dietary iodine is sufficiently low for an extended period such that thyroidal iodine stores become depleted. Such upregulation of thyroidal NIS leads to an increased number of NIS sites on thyroid follicle cells, which in turn has the impact of increasing iodine uptake and reducing the impact of competitive inhibition by perchlorate and other chemicals with NIS binding capacity such as nitrate, thiocyanate, and bromate. At relatively high doses of NIS competitive inhibitor agents in humans, the most immediate response is NIS upregulation, which restores thyroidal iodine uptake and reduces the effects of most environmental doses of exogenous NIS inhibitors.

The available evidence in studies of rats subjected to subchronic doses of perchlorate indicates solely reversible thyroid effects in perchlorate-treated adults and an important role of homeostatic mechanisms (e.g., NIS upregulation) in effects noted at doses (e.g., 1,000 ug/kg-day) more than 1000-fold higher than the perchlorate reference dose. Paulus et al. (2007) demonstrated that long-term iodine deficiency in rats leads to upregulation of NIS and increased resistance to as much as 5.6 mg/kg-day perchlorate inhibition of thyroidal iodine uptake. The highest dose of 28 mg/kg-day was reported to overwhelm the NIS upregulation in iodine deficient rats, leading to reduced thyroxine levels and corresponding TSH perturbations. Paulus et al. (2007) noted:

"The iodine-deficient animals in this study absorbed twice as much of an administered dose of 1311 into the thyroid as the iodine-sufficient animals (see Table 2). This increase in absorption by the animals on the iodine-deficient diet clearly outweighed other factors affecting absorption. This

increase in absorption is presumably preceded by elevation in release of TSH via the hypothalamus-pituitary-thyroid (HPT) axis, in response to low levels of thyroid hormone. It is known that upregulation of the thyroid by TSH is accompanied by increased expression of NIS (Kogai et al., 1997). Thus, nutritional deficiency in iodine induces the thyroid NIS system to be upregulated, increasing the population of NIS on the surface of the follicular cells. The time required for changes in T3, T4, and TSH in response to nutritional deficiency in iodine vary within species and nutritional states but it is known that changes in concentration of the NIS occur rapidly (within hours) in response to changes in the level of TSH (Eng et al.,1999; Yu et al., 2002). It is now understood that this upregulation occurs as a response to iodine deficiency, perhaps even in the absence of increases in TSH (Johnston et al., 2005). Moreover, during pregnancy, upregulation occurs both by rises in thyroid-stimulating hormone (TSH) and in response to higher titers of the hormone human chorionic gonadotropin (Glinoer, 1997). It is proposed that changes in NIS populations occur rapidly (within hours) and that this is the salient mechanism for control of iodine concentrations in the thyroid (Eng et al., 1999).

Analyses of the results of this study indicate that a second effect of this upregulation is that the NIS system becomes much more refractory to inhibition of iodide uptake by perchlorate ion. [...I]n order to restrict normal transport of iodide, a greater fraction of a larger population of NIS would need to be blocked, and this would require a higher concentration of perchlorate."

Yu et al. (2002) identified similar NIS upregulation that compensated for 0.1 to 3 mg/kg-day perchlorate in euthyroid rats; the highest dose of 10 mg/kg-day was reported to overwhelm the NIS upregulation in euthyroid rats, leading to reduced thyroxin levels and corresponding TSH perturbations. Yu et al. (2002) noted:

"In the present study, the up-regulated thyroid, under the influence of TSH, was able to overcome the blocking effects of perchlorate by increasing its capacity to sequester iodide and produce hormones. This is clearly a dose-dependent phenomenon, which was overwhelmed by the blocking effects of high serum levels of perchlorate. []

A 90-day rat study of ammonium perchlorate identified reversible thyroid hormone perturbations at doses of up to 1,000 mg/kg-day without effects on thyroid weight or histopathology or any effects on sperm parameters, estrous cycle, bone marrow, or serum hormones; the highest dose of 10 mg/kg did increase thyroid weight and follicular cell hypertrophy (Siglin et al., 2000). Thus, it appears that NIS upregulation in the face of iodine deficiency increases the number of thyroidal receptors, thereby diluting impacts of low (< 100 ug/kg-day) to moderate (< 1,000 ug/kg-day) doses of perchlorate on reversible inhibition of thyroidal iodide uptake."

Consistent with the above observations in rats, long-term iodine deficiency in humans is known to rapidly induce NIS upregulation that enhances iodine uptake from the diet and leads to TSH release to maintain circulating thyroxine levels (Andersen et al., 2001). Short-term and relatively mild iodine deficiency also leads to NIS upregulation coincident with normal thyroxine levels and slightly decreased TSH release due to increased sensitivity of thyrocytes and a greater number of thyrocytes participating in thyroid function (Brabant et al., 1992). Brabant et al. (1992) administered 900 mg/day (about 13 mg/kg-day in 3 divided doses) of perchlorate for 4 weeks in healthy male subjects in order to induce a short-term, mildly iodine-deficient state, which corresponded to an estimated 25% depletion in thyroidal iodine capacity. This high exposure regimen led to nominal changes in free thyroxine and near doubling of circulating thyroglobulin, the latter which may also represent an

adaptive response to iodine deficiency providing a greater thyroxine capacity in the form of thyroglobulin in the blood (Brabant et al., 1992).

Perchlorate has been used as a pharmaceutical agent in persons with abnormally high thyroxine production such as in Grave's Disease, with sufficiently high regular dosages (e.g., 6,000 to 28,000 ug/kg-day) resulting in reduction of circulating FT3 and FT4 levels to limit the availability of thyroidal iodide via NIS inhibition. However, lower doses in humans administered orally for several days to 6 months do not appear to significantly impact circulating levels FT3 or FT4 or TSH, or to change thyroid size, despite the demonstration of reduced efficiency (percentage of radioactive iodine uptake) of thyroidal iodide uptake (Lawrence et al, 2000, 2001; Greer et al., 2002; Braverman et al., 2006; Braverman, 2009). Also, studies of occupational and environmental perchlorate exposures have failed to reveal any significant impact on thyroid function at doses that in some cases greatly exceed the currently proposed reference dose of 0.7 ug/kg-day by more than 100-fold (Amitai et al., 2007; Tellez et al., 2005; Gibbs et al., 1998; Li et al., 2000a,b, 2001; Lamm et al., 1999; Braverman et al., 2005, 2006; Braverman, 2009; Gibbs and Landingham, 2008; Kelsh et al., 2003; Huffier et al., 2006; Chang et al. 2003; Crump et al., 2000; Gibbs et al., 2004; Leung et al., 2009; Pearce et al., 2007a,b).

With respect to sensitivity of the neonate life stage, Ginsberg et al. (2007) have argued that a combination of factors may put infants at greater risk, particularly during lactation. Because the breast is one of the extrathyroidal tissues known to express NIS, these researchers expressed the concern for potential adverse effects on neonatal growth and development due to the combination of possible iodine deficiency and possible accumulation of perchlorate (and depletion of iodide) in breast milk. Kirk et al. (2005) reported on iodide and perchlorate levels in dairy and breast milk in the United States and observed a linear correlation between increasing perchlorate and decreasing iodide among 36 human breast milk samples (perchlorate concentrations ranged from 0.6 to 92.2 ug/L, mean 10.5 ug/L; iodide concentrations ranged from 4.5 to 184.5 ug/L, mean 63.3 ug/L. However, the reported high correlation ($r2 > 0.9$) was based on only six breast milk samples with perchlorate levels over 10 ug/L (Kirk et al., 2005). Larger studies of iodine and perchlorate levels in breast milk (Pearce et al., 2007b) and colostrum (Leung et al., 2009) in Boston- area women reported no correlation of perchlorate to iodine in the mother's milk (including colostrum) or in urine.

With respect to sensitivity of the fetus life stage, pregnant females and their offspring in the fetal and neonatal stages, if thyroid deficient, have been postulated as being vulnerable to perchlorate toxicity to the thyroid, although this has not been demonstrated to date in human populations (Braverman, 2009). The available scientific studies do not point to increased prevalence of cretinism, maternal goiter, or neonatal hypothyroidism in the general U.S. population or in small populations with perchlorate in public water supplies (Amitai et at 2007; Leung et at 2009; Li et al., 2000, 2001; Buffler et al., 2006; Crump et al 2000; Kelsh et al., 2003; Gibbs et al., 2004; Chang et al., 2003).

McLanahan et al. (2009) reported a biologically-based dose-response model of the HPT axis coupled with a physiologically-based pharmacokinetic model of perchlorate in rats and concluded that perchlorate may have two modes of action: one involving inhibition of NIS and a second involving reduced production/release of thyroxine from the thyroid. They pointed to findings of Yu et al. (2002) who noted:

"Recovery of serum thyroid hormones from the blocking effect of the 1.0 and 3.0 mg/kg-day doses of perchlorate lagged behind the TSH induced up-regulation in thyroidal uptake of 125I. A TSH-

induced "iodide sufficient" condition was evident in the thyroid; however, serum thyroid hormones were persistently low for days. The reason for this is unknown but suggests that, at high doses of perchlorate that may initially saturate the symporter, perchlorate may cause secondary effects on the thyroid beyond competitive inhibition of thyroidal uptake of iodide."

However, rats are recognized to have considerably lower iodine storage capacity in the thyroid and hence may be expected to exhibit perturbations in circulating thyroxine and TSH more readily than would be expected in humans. McLanahan et al. (2009) also pointed to earlier studies indicating perchlorate may displace iodide on certain binding proteins at very high concentrations in vitro (Okabe and Hokaze, 1993; Yamada, 1967), and to recent reports that perchlorate is probably concentrated in thyroid cells at high doses (Tran et al., 2008; Dohan et al., 2007). McLanahan et al. (2009) concluded that,

"A significant correlation of effects of ClO4- with serum thyroid hormones in humans has yet to he confirmed, so the importance of this potential mode of [mode of action] in humans is not known."

Moreover, the observed high dose effects on protein binding and on accumulation of perchlorate in the thyroid are reversible and not likely to be relevant to environmental perchlorate exposure levels in humans and are not associated with thyroid pathology at moderate dosages (e.g., 100-1,000 ug/kg-day) in normal and iodine-deficient rats based on detailed assessments (Paulus et at, 2007; Yu et al., 2002; Siglin et al., 2000).

In regards to sensitivity of different life stages to perchlorate thyrotoxicity, research is needed to examine the nature and extent of NIS upregulation in iodine deficient newborns and neonates, as well as assessment of the natural capacity of thyroidal iodine stores at birth to buffer any impacts on circulating thyroxine when iodine intake is relatively low or intermittent. It is generally known that thyroid deficiency leads to NIS upregulation (and increased thyroid volume) in pregnant and nonpregnant adults as well as in neonates, although the capacity of this protective mechanism is not well characterized in pregnant women or neonates. Consistent with the expected presence of NIS upregulation in mothers and infants, the available scientific studies do not point to increased prevalence of cretinism, maternal goiter, or neonatal hypothyroidism in the general U.S. population or in populations with higher perchlorate levels in public water supplies (Amitai et al., 2007; Leung et al., 2009; Li et al., 2000, 2001; Buffler et al., 2006; Crump et al., 2000; Kelsh et al., 2003; Gibbs et al., 2004; Chang et al., 2003).

In summary, although high doses of perchlorate 1,000 ug/kg-day) for extended time periods can cause reversible perturbations in thyroid function, such impacts have not yet been demonstrated at moderate doses (< 100 ug/kg-day) or the relatively low environmental doses (< 10 ug/kg-day) likely to be relevant to drinking water exposures. These findings, largely in human studies, suggest that the EPA-adopted reference dose of 0.7 ug/kg-day is a conservative and health- protective reference dose that incorporates a 10-fold uncertainty factor applied to the point of departure (7 ug/kg-day) to account for differences between healthy adults and the most sensitive population: fetuses of pregnant women who might have hypothyroidism or iodide deficiency.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p.

41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

EPA Comment Code: 2500

Comment: Data shows that perchlorate is actively transported into mammary epithelial cells by the sodium iodide symporter (NIS), resulting in an accumulation of perchlorate in breast milk.[FN47: Dohan, O, C Portulano, C. Basquin, A Reyna- Noyra, LM Amzel, and N Carrasco. 2007. The Na+/I- symporter (NIS) mediates electroneutral active transport of the environmental pollutant perchlorate. PNAS 104(51):20250-20255.][FN48: Dasgupta, P. K., Kirk, A. B., Dyke, J. V., and Ohira, S.-I. (2008). Intake of Iodine and Perchlorate and Excretion in Human Milk. Environ. Sci. Technol. 42, 8115-8121.] These data suggest that perchlorate may not only inhibit iodide accumulation in maternal milk but also would be transferred in breast milk to the nursing infant where it would be predicted to inhibit iodide uptake in the infant's thyroid gland. The NIS also is found in the placenta and based on this new research it seems likely that perchlorate is actively transported across the placenta. Because the fetus and developing infant require adequate iodide for thyroid hormone function, any determination of a safe level of exposure to perchlorate should take into account this mode of action for perchlorate toxicity.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: c. On the most appropriate data to estimate alternative HRLs

NRDC response: The CDC (2006/2007) data represent the best available data.

The derivation of a health-based standard for perchlorate should reflect the best available data, including published data collected and analyzed by the CDC and described by Blount et al (2006) and Blount et al (2007).[FN49: Blount BC, Valentin-Blasini L, Osterloh JD, Mauldin JP, Pirkle JL. Perchlorate exposure of the US Population, 2001-2002. J Expo Sci Environ Epidemiol. 2007 Jul;17(4):400-7. Epub 2006 Oct 18. Blount BC, Pirkle JL, Osterloh JD, Valentin- Blasini L, Caldwell KL. Urinary perchlorate and thyroid hormone levels in adolescent and adult men and women living in the United States. Environ Health Perspect. 2006 Dec;114(12):1865-71.] The CDC data have the following significant advantages over the Greer et al data used by EPA:

1. Although the CDC data are from a cross-sectional analysis, because the survey includes a large number of individuals, the variability represents random error, not bias, and the data are likely to be representative of chronic perchlorate exposure; 2. The number of individuals included in the CDC study are sufficient for the specific analysis of a sensitive subpopulation defined as women with low iodine intake; 3. A benchmark dose (BMD) analysis of perchlorate-related modulation of serum thyroid hormone concentrations is feasible; and 4. Perchlorate exposures, as measured by urinary perchlorate concentration, corresponding to the benchmark dose low (BMDL) can be converted to an estimated dose in mg/kg-day, that can be used as the point of departure for the derivation of both the MCL and HRL.

From Blount et al (2006) we know that the mean for total serum T4 concentrations in women is 8.27 ug/dL and the 25th percentile of perchlorate exposure (equivalent to 1.6 ppb perchlorate in urine) is associated with a 10% drop in total serum T4 in women with low iodine intake.[FN50: Blount BC, Pirkle JL, Osterloh JD, Valentin-Blasini L, Caldwell KL. Urinary perchlorate and thyroid hormone levels in adolescent and adult men and women living in the United States. Environ Health Perspect. 2006 Dec;114(12):1865-71.] Importantly, the unique physiology of pregnancy and interactions between the mother and fetus make both especially susceptible to the harmful effects of perchlorate; maternal T4 is the only source of thyroid hormone for the fetus in the first trimester.

Blount et al (2007) established that for women with low iodine intake (defined by the World Health Organization as urinary iodine < 100 ug/L),[FN51: World Health Organization (WHO). 1994. Indicators for assessing iodine deficiency disorders and their control through salt iodization. WHO/NUT/94.7. Geneva: WHO/International Council for the Control of Iodine Deficiency Disorders.] very low levels of perchlorate exposure were associated with decreased serum T4 and increased serum TSH; the CDC estimates that 36% of U.S. women have iodine intakes in this range. For iodine-sufficient women (defined as urinary iodine >= 100 ug/L), perchlorate exposure was associated with increased TSH. Increased TSH is an indicator that the body is attempting to compensate for a decrease in thyroid hormone production, and is clinically considered to be a more sensitive marker of subtle thyroid alteration than depressed levels of serum T4. When predicting changes in serum TSH with increasing perchlorate exposures, women with low iodine intake and TSH levels on the high end of the normal range (> 3.11 IU/L) appeared to be the most sensitive group. In this group, any increase in urinary perchlorate predicted an increase in TSH that was consistently more than twice the predicted increase in TSH for women with low iodine levels and

median TSH levels. For unknown reasons, perchlorate was not associated with T4 or TSH levels in men. The observed changes in serum T4 and TSH in women are consistent with our understanding of how thyroid hormones are regulated in the body, and with the mechanism of toxicity of perchlorate.

Importantly, the extremely low levels of perchlorate were associated with thyroid hormone disruptions - and the magnitude of these disruptions. The CDC researchers found that if a low iodine woman started with perchlorate exposure corresponding to 0.19 ppb in urine (the minimum level found), and then ingested enough perchlorate through food and/or drinking water to raise her urinary perchlorate level to 2.9 ppb (the median level found), her T4 levels would drop by 13%.[FN52: The drop in T4 predicted to be 1.06 ug/dL; the percentage decrease is calculated as compared to the average T4 level found in the CDC study (8.27 ug/dL).] Similarly, if her urinary perchlorate level increased to 5.2 ppb (the 75th percentile exposure), her T4 levels would drop by 16%. The maximum level of perchlorate exposure found was 100 ppb, which translated into a 29% decline in T4.

d. On the merits of the approach EPA used to derive HRLs

NRDC response: The Greer data no longer represent the best available data.

Because the dose-response relationship used to determine the RfD is derived exclusively from the Greer et al study, the HRL also is dependent on the Greer et al study to determine the maximum allowable level of drinking water contamination.

The Greer et al study [FN53: Greer MA, G Goodman, RC Pleus, and SE Greer. 2002. Health effects assessment for environmental perchlorate contamination: the dose- response for inhibition of thyroidal radioiodine uptake in humans. Environ Health Perspect 110:927-937.] reported on study results from intentional dosing of a small population (N=37) of healthy men and women, for only two weeks. That is, the study cannot represent realistic chronic exposure scenarios, and it cannot be considered representative of the U.S. population including infants and children. Moreover, the study lacked measurements of iodine status that is now known to be a critical variable. Other significant weaknesses with the Greer study included the fact that the low dose group contained only seven participants including only six women. Use of these limited data to calculate a regulatory trigger level has been widely criticized as inadequate by state scientific experts[FN54: Ginsberg G and D Rice. The NAS perchlorate review: questions remain about the perchlorate RfD. Environ Health Perspect. 2005 Sept; 113(9):1117-9. Erratum in: Environ Health Perspect. 2005 Nov; 113(11):A732.] and by EPA's own Children's Health Protection Advisory Committee,[FN55: Letter from Melanie Marty to Administrator Johnson regarding Preliminary Regulatory Determination on Perchlorate (November 3, 2008, PDF) http://yosemite.epa.gov/ochp/ochpweb.nsf/content/perchlorateletter.htm/$file/PerchlorateLetter.pdf] and no longer reflects the best available data.[FN56: EN Pearce, AM. Leung, BC Blount, HR Bazrafshan, X He, S Pino, L Valentin-Blasini, and LE Braverman, 2007. Breast milk iodine and perchlorate concentrations in lactating Boston-area women. J Clin Endocrinol Metab. 92(5):1673-7.] [FN57: Letter from Melanie Marty to Administrator Johnson regarding Preliminary Regulatory Determination on Perchlorate (November 3, 2008, PDF) http://yosemite.epa.gov/ochp/ochpweb.nsf/content/perchlorateletter.htm/$file/PerchlorateLetter.pdf] Despite these limitations, careful analysis of the Greer data reveal clear evidence of perchlorate toxicity in the low-dose group; three subjects showed no perchlorate effect, but four

subjects in the low-dose group had a measurable decrease in iodide uptake commensurate with perchlorate exposure.[FN58: For a complete analysis of the NAS review of perchlorate, see: Ginsberg G and D Rice. The NAS perchlorate review: questions remain about the perchlorate RfD. Environ Health Perspect. 2005 Sept; 113(9):1117-9. Erratum in: Environ Health Perspect. 2005 Nov; 113(11):A732.] Because the study authors relied on averaged data rather than individual data, the more sensitive individuals in the study group were obscured

The short duration of the Greer study, only 14 days, mean that the cumulative effects of longer-term exposure are not accounted for. A study in rats found greater perchlorate toxicity to the thyroid from 90-day exposure than from 14- day exposure (Springborn Laboratories 1998), suggesting that cumulative exposure may cause significant systemic injury that is not detectable in a short-term study. Although one sub-chronic (six month) human study with 13 volunteers has been promoted by industry as indicating that humans adapt to long-term exposure (Braverman et al. 2006[FN59: Braverman LE, EN Pearce, X He, S Pino, M Seeley, B Beck, B Magnani, BC Blount, and A Firek. 2006. Effects of six months of daily low-dose perchlorate exposure on thyroid function in healthy volunteers. J Clin Endocrinol Metab. Jul; 91(7):2721-4. Epub 2006 Apr 24.]) this study was unlikely to have adequate statistical power to detect an effect because it failed to consider the widely-recognized vulnerable populations, including infants, children, and women with low dietary iodide. The Blount (2006) study showed that these populations are much more vulnerable to perchlorate toxicity than the average population; women are more sensitive than men, iodine-deficient (urinary iodide below 100 ug/L) women are more sensitive than iodine-sufficient women, and iodine-deficient women with TSH levels on the high end of the normal range are even more sensitive than other iodine-deficient women.[FN60: Blount BC, Pirkle JL, Osterloh JD, Valentin-Blasini L, Caldwell KL. Urinary perchlorate and thyroid hormone levels in adolescent and adult men and women living in the United States. Environ Health Perspect. 2006 Dec;114(12):1865-71.] Other human studies suffer from the same limitations as the Greer study. For example, a study of chronically perchlorate-exposed pregnant women in Chile[FN61: Tellez RT, PM ChacÃ³n, CR Abarca, BC Blount, CB Van Landingham, KS Crump and JP Gibbs. 2005. Long-term environmental exposure to perchlorate through drinking water and thyroid function during pregnancy and the neonatal period. Thyroid 15(9):963-975.] that also failed to find an effect of perchlorate exposure had only three iodine-deficient female subjects out of 183 in total.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: Iodine Deficiency and the IG Report

In addition to NAS, at least one peer reviewer, several researchers (Amitai et al., 2007, Crump et al. 2004, Braverman 2007, Tellez et al. 2006) and EPA's IG (December 2008 external review draft document, Scientific Analysis of Perchlorate) have suggested that iodine deficiency is the public health problem with respect to thyroid malfunction more so than perchlorate. Furthermore, the IG report suggests that improving the iodide nutrition level for pregnant and nursing women is the most effective way to prevent low maternal total iodide uptake.

The draft report also states that because perchlorate is only one of many chemicals that affect iodide uptake in the thyroid, EPA should have followed a cumulative risk assessment approach in its perchlorate risk assessment. EPA's only mention of the IG report in the NODA is to acknowledge that the IG Report commented that the agency's risk assessment " account for the activity of other compounds with similar actions on the thyroid." The FR then directs the reader to section III.C.2 for more information, but III C. 2 details issues raised by commenters regarding the occurrence analysis and not the risk assessment or the IG report.

AMWA recommends that the final IG report be released to the public and its recommendations considered in EPA's final regulatory determination, particularly with respect to the cumulative risk assessment and iodine deficiency.

The Science of Perchlorate

Several peer reviewers of EPA's PBPK model as well as the peer reviewers of EPA's 2008 health advisory referenced new studies that EPA failed to mention in this NODA. It is important for EPA as a scientific agency to objectively and correctly characterize the science of perchlorate in the regulatory determination, and consider the body of epidemiological data as well as other health and occurrence information, particularly because the topic of possible effects to pregnant women, infants and children is such an emotional one. Much has been written in the media about perchlorate and its effects and the public and decision makers look to the agency as well as to organizations like NAS to help interpret what the science is telling us.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA does not disagree that a total iodine inhibitor load, including naturally-occurring NIS inhibitors, should be considered. The Administrator of EPA has suggested a new approach that considers cumulative risks of chemical mixtures. At this time we have not given this option full consideration. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other

factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: In previous exposure assessments conducted by the EPA, such as arsenic, all available epidemiological data was factored into the modeling assumptions, including sensitive subpopulations. EPA has clearly omitted significant peer- reviewed studies that provide a significant weight of evidence finding that there is no adverse impact from exposure to perchlorate in drinking water in the subpopulations that are a focus of this reassessment as summarized in Table 1. This omission represents a significant deficiency that countermands the Agency's stated commitment [FN3: Memo to Employees from EPA Administrator Lisa Jackson, entitled "Scientific Integrity: Our Compass for Environmental Protection". May 9, 2009. http://www.epa.gov/Administrator/scientificmemo.html] and obligation under the SDWA to use the "best available peer reviewed science" for supporting sound and technical regulatory determinations.

Table 1. Epidemiological Studies Assessing Effect of Perchlorate Exposure on Children [see PDF docket ID EPA-HQ-OW-2009-0297-0415]

Comment: Dohan et al. (2003) provide perhaps the most comprehensive review of the NIS regulation at the time of the NRC report. Dohan et al. reported that "up-regulation of thyroid NIS

expression and iodide uptake activity by TSH has been demonstrated not only in rats in vivo but also in the rat thyroid-derived FRTL-5 [Fisher rat thyroid cell line] cell line and in human thyroid primary cultures. TSH up-regulates iodide uptake activity by an increase in NIS transcription. They say: Both NIS mRNA and NIS protein levels decreased significantly after either 1 or 6 days of iodide administration. NIS mRNA levels were already significantly reduced at 6 hours following the injected single dose of iodide. In contrast, a significant decrease of NIS protein levels was detected only at 24 hours. After TSH withdrawal, a reduction of iodide uptake activity is observed in FRTL-5 cells. This is a reversible process, as iodide uptake activity can be restored by TSH. The NIS half-life is approximately 5 days in the presence and approximately 3 days in the absence of TSH (Dohan et al., 2003). Other studies support up- regulation of NIS during changing levels of iodine (e.g., Eng et al., 1999; Wagner et al., 2002; Merrill et al., 2003; Pedraza et al., 2006; Norden et al., 2007; and Bizhanova and Kopp, 2009).]

Comment: At a recent symposium on perchlorate held in conjunction with the annual Society of Toxicology (SOT) meeting in Seattle, Lamm et al. (2008) presented their initial reanalysis of the NHANES dataset used by Blount et al. (2006) with an adjustment for urinary creatinine. Lamm et al. considered a subset of women from the Blount et al. (2006) study who were of childbearing age (15-44 years old; the Blount et al. (2006) study group included all women over the age of 12) as well as the interaction of thiocyanate and nitrate, both in urine. They found there was no significant association between perchlorate and total T4, including women with urinary iodide less than 92 ug/g (Figure 3).

Figure 3. Urinary reanalysis results of the NHANES data [see PDF docket ID EPA- HQ-OW-2009-0297-0662]

In a peer-reviewed letter to the editor of Thyroid, Gibbs and Van Landingham (2008) reviewed data from their previously published study (Tellez et al., 2005), and showed that in a cohort of pregnant women in Chile, the data do not support the association between environmental perchlorate

exposure and changes in thyroid hormones and are consistent with the recent negative findings by both Pearce et al. (2007a) and Lamm et al. (2008), both presented at the Seattle SOT meeting.

More recently, Mendez et al. (2009) used probabilistic modeling to estimate the total dose of perchlorate from food and drinking water using three drinking water scenarios based on UCMR1 data. The highest estimated dose through water and food was 0.15 ug/kg-d at the 95th percentile, well below the RfD of 0.7 ug/kg-d. When compared to the NHANES 2001-2002 estimates based on urinary output (used by Blount et al.), they found that intraday variability contributed to the overestimation of dose based on the NHANES data. Interestingly, they also found that the urinary excretion of perchlorate in NHANES 2003-2004 was significantly lower than in 2001-2002. Two data points do not represent a trend, but this lower urinary excretion may represent lower doses through food and water in subsequent NHANES studies.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: Steinmaus et al. (2007)

Steinmaus et al. (2007) used the same dataset as Blount et al. (2006) to assess the correlation between smoking, thiocyanate and urinary perchlorate, and thyroid hormone levels. The same methodological issues reported for Blount et al. (2006) apply to this study. As in Blount et al. (2006), the authors did not find any interaction between perchlorate and smoking and TSH or total T4 in women with urinary iodine levels greater than or equal to 100 ug/L or in men. They did conclude that in women with urinary iodine less than 100 ug/L, perchlorate increased the risk of lower total T4 and higher TSH, just as was reported in the Blount et al. study. This association was stronger when the woman was also a smoker or had high urinary thiocyanate levels.

Amitai et al. (2007)

This ecological study aimed to "...assess the effect of gestational perchlorate exposure through drinking water on neonatal thyroxine (T4)" by comparing T4 levels among newborns whose

mothers lived in areas with drinking water perchlorate levels associated with "very high exposure" (10 to 100-fold greater compared to levels in the U.S.; >=340 ug/L), "high exposure" (42-94 ug/L), or "low exposure" (<3 ug/L). T4 levels were measured within 36 to 48 hours after birth but there was no comment on whether the infants were breast fed or formula fed during the postnatal period. The authors found that there were no differences between neonatal T4 levels among the groups. This study provides evidence that the current RfD and values greater are conservative and health protective to the most sensitive individuals in the population.

Pearce et al. (2007)

The objective of the Pearce et al. study was "to determine whether breast milk iodine concentrations in Boston-area women are adequate for infant nutrition, and whether breast milk iodine concentrations may be associated with environmental perchlorate or cigarette smoke exposure." Pearce et al. measured breast milk iodine and perchlorate concentrations as well as iodine, perchlorate, and cotinine in urine. They then compared the levels found in breast milk to 17 commercial infant formulae. Neither breast milk nor urinary perchlorate levels were significantly correlated with breast milk iodine concentrations. Although perchlorate was detectable in infant formulae, the levels were lower than in breast milk. A significant number of women in this study had iodine levels that were insufficient to meet the infant's needs, but the authors did not suggest this was due to perchlorate exposure or that it represents a chronic iodine deficiency.

Kirk et al. (2005)

With the aim to determine what amount of perchlorate children are exposed to, Kirk et al. measured perchlorate and iodide levels in cow and human breast milk and compared these values to corresponding levels of perchlorate in drinking water in the area. Perchlorate was measurable in 81 of the 82 samples. The average perchlorate levels in cow milk and human milk were 2 and 10.5 ug/L, respectively. The maximum levels in cow and human milk were 11 and 92 ug/L, respectively. There was no correlation between levels of perchlorate in breast milk and perchlorate in drinking water. The authors speculated that there was a correlation between higher levels of perchlorate and lower levels of iodine in breast milk; however, they note that this relationship only existed for the breast milk samples with the highest perchlorate levels (6 subjects out of 82). The authors recognize that this relationship may be coincidental due to the small number of samples with perchlorate levels greater than 10 ug/L, stating that "If we take all the available data, there is no meaningful correlation between the perchlorate and iodide levels in breast milk." As with previous studies, due to the design, this study was not able to evaluate a causal relationship.

Kirk et al. (2007)

To determine the variability in the excretion of perchlorate, thiocyanate, and iodide in human milk, Kirk et al. had lactating women collect six samples of milk on each of three days or as many samples as possible over three days. They found that a significant variation over time for all the anions tested. The average iodide, perchlorate and thiocyanate levels were 87.9 ug/L, 5.8 ug/L, and 35.6 ug/L, respectively. The study was not designed to determine whether perchlorate or thiocyanate contributed to IUI in mammary tissue. This study was a biomonitoring study and did not measure any adverse effects or exposures.

Dasgupta et al. (2008)

"The objective of this present study was to study the excretion of perchlorate, thiocyanate, and iodine in milk and urine and relate the observed pattern within the broad framework of parallel/competitive transport by the NIS." Using breast milk and urine samples from 13 lactating women and using EPA default values for infant body weights and milk intakes, the authors mathematically modeled infant intakes and doses of iodide, perchlorate, and thiocyanate. They calculated the fraction of iodide, perchlorate, and thiocyanate in breast milk compared to the total that is excreted in both breast milk and urine. They used a ratio of these fractions in milk to determine the selectivity of either perchlorate or thiocyanate over iodide. They report "that 12 of 13 infants did not have an adequate intake of iodine...and 9 out of 13 infants were likely ingesting perchlorate at a level exceeding the reference dose..." They also concluded that the selectivity of perchlorate over iodide was 3.14+/-1.2.

There are a number of unresolved issues related to the experimental design of this paper. The population is small and there is no information on the selection process of the participants (i.e., they are not a random sample). Only three biological variables were measured in the women. The rest of the variables, including the variables used to derive the conclusions, are calculated from these three or are default values for infant intake and infant weights. The three measurements were the concentrations of perchlorate, iodine, and thiocyanate in urine and breast milk. Where other research has measured more biologically relevant information, such as serum concentrations of analytes that would be most reflective of relative concentrations at the NIS (Tonacchera et al., 2004; Pearce et al., 2007), this work is based on very few measured observations. The estimated doses, the key variable for understanding possible effects, are based on average body weight and intakes for an infant. For such a simple and critical variable and in such a small study population, it is surprising that actual body weights were not measured.

In addition to study design, the data presented in this paper appear to contradict the interpretation by the authors of the paper. Based on estimated weights, the authors say that nine out of 13 infants are consuming daily doses in excess of the RfD, yet Table 1 of Dasgupta et al. suggests there are 8 infants who exceed the RfD of 0.7 ug/kg-d (subjects 1, 2, 8, 11, 13, 15, 16, 20). Furthermore, if one reviews these estimates to measured variables, the infants with estimated perchlorate doses greater than the RfD are also estimated to have the greatest iodine intake. By plotting the values for total iodide excretion (column 4), total perchlorate excretion (column 7), estimated maternal breast milk iodide excretion (equivalent to estimated infant iodide intake; column 5), and estimated maternal breast milk perchlorate excretion (product of total perchlorate excreted and percent of perchlorate in milk; column 7 x column 9) found in Table 1 of the paper, the results demonstrate that perchlorate and iodide are positively correlated (See Figure 4). If perchlorate was inhibiting the transport of iodide into milk, the association would be negative.

Figure 4. Plotting of data reported by Dasgupta et al., 2008 to illustrate the association between concentrations of iodine and perchlorate in urine and milk in lactating women. [see PDF docket ID EPA-HQ-OW-2009-0297-0662]

In addition to the questions regarding interpretation of the data presented in this paper, there are concerns about the interpretation of their previous work (Kirk et al., 2005) and how that study impacts this recent study. For example, Dasgupta et al. (2008) remark that "in real mothers perchlorate does inhibit the transport of iodine into milk and because of competitive inhibition both analytes cannot be high at the same time." This statement, however, is based on a previous study in

which the researchers defined their cut off values[FN16: The cut off values from Kirk et al. (2005) were defined as follows: High iodide in breast milk was greater than 60 ug/L and high perchlorate in breast milk was greater than 20 ug/L.] above which milk iodide or perchlorate was considered "high." They report that no milk samples had both high perchlorate and high iodide (Kirk et al., 2005). In the present study, they report the same trend although they do not define a cut off value. Yet if the previous cut off values are applied to the current study, there are many samples that had simultaneously high perchlorate and iodide (Figure 4). Based on the previous conclusions about competitive inhibition of analytes (Kirk et al., 2005), this study does not demonstrate that perchlorate competitively inhibits iodide transport into milk at the concentrations experienced by these women.

Schier et al. (2009)

The authors measure the concentration of perchlorate in reconstituted powdered infant formula and used this information to estimate a mean and upper-bound dose of perchlorate in infants solely fed formula. They also estimated the perchlorate concentration in water that would cause an infant in the 10th, 50th or 90th percentile of body weight to receive a dose equal to the RfD every day. The authors concluded that some infants could be at risk for exceeding the RfD even with minimal amounts of perchlorate in water used for reconstitution, but "the clinical relevance of exceeding the perchlorate RfD in both an iodide-sufficient and iodide-deficient state are unclear."

This study provides information to the literature on potential exposures given that all the assumptions made about exposure hold true. This study is focused on the exclusively formula fed infant. The most sensitive subpopulation for perchlorate health effects and the group that the RfD is based, is fetuses of hypothyroid mothers. This paper compares the RfD to estimated doses in a population that is not the considered the most sensitive. The RfD is an

...estimate with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime.

This report does not demonstrate that this population is receiving doses of perchlorate at or above the RfD. This study suggests that some individuals have the potential to exceed the RfD, if all the assumptions implied hold true. Exceeding the RfD is not or meant to be a bright line threshold of effects. As noted above, the perchlorate RfD is based on a NOEL in addition to an UF adjustment.

McLanahan et al. (2009)

In an attempt to evaluate the mode of action of perchlorate, McLanahan et al. coupled a biologically-based dose response model of the hypothalamic-pituitary- thyroid axis with a PBPK model for perchlorate. The model was based on rats and evaluated changes in serum thyroid hormones with exposure to doses of perchlorate up to 10 mg/kg-d (a DWEL of 350,000 ppb). With this high dose, the authors found that the model outputs were inconsistent with observed data from experimental studies (Yu et al., 2002). The authors must add a numerical adjustment factor to their model so that output from the model agrees with experimental data. They conclude that:

ClO4- administered in drinking water (or by other routes of administration) interacts with the rat thyroid gland itself, potentially altering thyroid hormone synthesis or secretion. This interaction is in

addition to blocking thyroidal uptake of iodide. Current presumptions of a single MOA for ClO4- on the HPT axis do not appear tenable based on these results.

Modeling can be very valuable in research. This model, however, is based exclusively on rats. As many have noted, rat and human thyroid endocrinology must be evaluated carefully as the differences between the two species are important. Rats have smaller stores of thyroid hormones and are more sensitive to IUI than humans (NRC, 2005). This model is not able to predict output that is consistent with observed experimental data. Thus, without the addition of a numerical adjustment factor (called the "proportional inhibition term") this model does not produce comparable results to experimental data. The need for this numerical adjustment factor suggests unaccounted data needs or terms in the model, a species difference, or the effects of pendrin given the higher dose levels. The authors say no more than what is quoted above and provide no additional information as an explanation.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Water Docket Environmental Protection Agency Mailcode: 2822T 1200 Pennsylvania Ave., NW. Washington, DC 20460

Re: Docket ID No. EPA-HQ-OW-2009-0297, Perchlorate Supplemental Request for Comments

To Whom It May Concern:

The Association of California Water Agencies appreciates the opportunity to comment on the United States Environmental Protection Agency's Supplemental Request for Comments on the perchlorate regulatory determination. ACWA represents over 450 public water agencies in California that collectively supply over 90% of the water delivered in California for domestic, agricultural and industrial uses. ACWA agencies are integrally involved in all aspects of surface water and groundwater management statewide to ensure that water supply needs are adequately addressed and are committed to ensuring that drinking water is safe for customers throughout California.

ACWA and its members have a long record of supporting a timely and consistent standard setting process, both at the state and federal levels, developed through regulatory channels and governed by good science. This support extends to the USEPA regulatory determination for perchlorate. In California we have worked diligently with the Office of Environmental Health Hazard Assessment (OEHHA) and the Department of Public Health (DPH) on many drinking water regulations, including the recent adoption of a maximum contaminant level of 6 parts per billion for perchlorate.

As the Environmental Protection Agency reviews its initial regulatory determination for perchlorate including the potential options for evaluating whether there is a meaningful opportunity for human health risk reduction from perchlorate through a national primary drinking water regulation, ACWA would like to offer the following comments for consideration in addition to responses for questions posed by USEPA: Â Issues for consideration: Â 1) USEPA should carefully consider important epidemiological data when reviewing their regulatory determination.

In four recent rule-making efforts by the USEPA involving arsenic, disinfection byproducts (DBPs), radon, and uranium, the risk assessments are based entirely on epidemiological data. In the case of arsenic and DBPs, they devote significant time and resources to reviewing numerous epidemiological studies with one study selected in each case to actually quantify the risk.

For example, the Federal Register Notice of the Arsenic Rule had almost three pages of discussion of the epidemiological data (7025 - 7027) including reference to epidemiological papers Lewis et al., 1999, Buchet et al., 1999; Kurttio et al., 1999, Chen et al., 1985; 1988; 1992; Wu et al., 1989, Hopenhayn- Rich et al., 1996; 1998, Smith et al., 1998, Morton et al., 1976; Valentine et al., 1992; Wong et al., 1992. In spite of several recent and well-designed studies available for review, the perchlorate regulatory determination appears to be the only instance where the epidemiological literature was not sufficiently considered.[FN1: Crump et.al., 2000, Tellez et.al., 2005, and Amitai et.al., 2007] Because USEPA routinely incorporates epidemiological data into these sorts of regulatory determinations, they should do so in this case as well.

Response: EPA acknowledges and thanks you for providing additional information related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other

factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: The most recent studies show widespread exposures:

The notice in the Federal Register concludes with a section that discusses studies published since EPA adopted the NAS RfD for perchlorate. Since EPA adopted the NAS RfD of 0.7 ug/kg/day, several comprehensive studies have been published that shed new light on the degree of perchlorate contamination in the United States and the possible health implications of this contamination. In a fact sheet that accompanied the August 19th notice in the federal register, the agency notes, "The key focus of the re-evaluation has been consideration of exposure of infants and young children." EWG fully supports this renewed focus on the health threats that perchlorate presents for infants and young children. Research from the last few years has established that not only do infants and children have higher exposures to perchlorate when compared with adults, they are also more vulnerable to its toxic effects. A comprehensive epidemiological study from the CDC also calls into question the safety of the current RfD (Blount et al 2006b). Below, we list the evidence from recent research that confirms that infants and children are particularly at risk from perchlorate contamination of drinking water and why EWG believes that a maximum contaminant level (MCL) of no higher than one ppb is a necessary public health measure:

- A major CDC bio-monitoring study found that children ages six to 11 have higher exposure to perchlorate compared with adults (Blount et al 2006a) - An FDA study that found perchlorate contamination of 74% of nearly 300 types of commonly consumed foods and beverages also confirmed that young children are exposed to more perchlorate, per unit of body weight, from contaminated food when compared with adults (Murray et al 2008) - A recent study from CDC scientists found that powdered infant formula is widely contaminated with perchlorate (Schier et al 2009) - Infants and children require more iodine on a body weight basis than adults and could therefore be more vulnerable to a thyroid toxin like perchlorate that inhibits iodine uptake by the thyroid gland (WHO 1998) - Breast milk testing in the U.S. has revealed wide-spread contamination with perchlorate (Kirk et al 2005, Kirk et al 2007, Pearce et al 2007) - Adequate levels of thyroid hormones are critical to normal brain development in infants and children and even subtle decreases in these hormones during these critical periods can have irreversible effects on cognition (Haddow et al 1999, Pop et al 1999) - A major epidemiological study from the CDC finds that perchlorate exposures far below the current RfD are associated with significant changes in thyroid hormone levels in women (Blount et al 200b)

Each of these points is further discussed in detail below:

CDC bio-monitoring study finds that children have higher perchlorate exposure: In 2006, CDC scientists published the results of a major bio-monitoring study in which nearly 3,000 Americans

ages six and older who are representative of the U.S. population were tested for perchlorate. Every single participant was found to have been exposed to perchlorate. Furthermore, children ages six to 11 had the highest exposure of any group tested, with urinary perchlorate levels that were 1.6 times higher on average than in adults (Blount et al 2006a).

As far as EWG is aware, there has been no testing of urinary levels of perchlorate in children under the age of six or infants in the United States. While this is a significant data gap, there is reason to believe that infants and young children may be among the most highly exposed groups in this country. Infants are at risk for high exposures to perchlorate due to widespread contamination of breast milk and infant formula, while young children are especially at risk due to widespread food contamination, especially of dairy products such as cow's milk. Widespread contamination of foods that infants and young children consume heavily coupled with the fact that children consume more food and water per unit of body weight than adults and their relatively small size in comparison with adults virtually guarantees that infants and young children have even higher perchlorate exposures than children in the six to 11 age group and adults.

FDA finds widespread perchlorate contamination of commonly consumed foods and beverages: In 2008, scientists from the FDA published the results of a study in which 285 commonly consumed foods and beverages were tested for perchlorate. Their results revealed widespread food contamination in the U.S.; perchlorate contaminated 74% of foods and beverages that were tested. The FDA scientists went on to estimate daily perchlorate exposures from contaminated foods and beverages (excluding tap water) and found that exposures were highest among two year olds. For this age group, perchlorate exposures from contaminated food and beverages ranged from 50 and 56% of the current EPA RfD of 0.7 ug/kg/day (Murray et al 2008).

The FDA findings are especially concerning because they show that children have high baseline exposures to perchlorate from commonly consumed foods and beverages. Overall, the FDA analysis found that children ages 10 and under are most highly exposed to perchlorate from contaminated foods and beverages. This is because children consume items from food groups that are heavily and consistently contaminated with perchlorate, especially dairy foods. In addition, their smaller size in comparison with adults means that, pound for pound, they are exposed to higher amounts of perchlorate than adults.

The FDA study, while concerning in itself, has even more profound implications for the children who live in any one of the 26 states in which perchlorate has been found in drinking water. EWG analysis finds that every proposed or final drinking water standard for perchlorate in the U.S. fails to protect two year olds from routine, daily, unsafe exposure when combined food and water exposures are considered. A two-year-old of average size could exceed EPA's current RfD by drinking water with just four ppb of perchlorate contamination (EWG 2008). A two-year-old of smaller size or with above average daily water consumption could easily exceed the RfD at even lower drinking water concentrations. The widespread food contamination by perchlorate leading to high baseline perchlorate exposures among children underscores the need to set an MCL of <1 ppb to minimize combined food and tap water exposure among children.

CDC scientists find perchlorate in infant formula: Earlier this year, CDC scientists published results of a study in which they tested 15 brands of infant formula; they found perchlorate contamination of all brands tested. The two most contaminated brands, made from cow's milk, accounted for 87% of the U.S. powdered formula market in 2000. The CDC team warned that mixing perchlorate-

tainted formula powder with tap water containing "even minimal amounts" of the chemical could result in exposures that exceed the current RfD. For example, they note that "reconstitution of PIFs (powdered infant formulas) with water containing perchlorate levels of at least 4 ug/l resulted in 26/48 (54%) dosing scenarios exceeding the RfD". In several other dosing scenarios, the formula was so heavily contaminated with perchlorate that formula consumption alone resulted in exposure levels above the RfD (Schier et al 2009). This study again underscores how easily vulnerable populations such as formula fed infants can exceed EPA's perchlorate RfD when cumulative exposures from contaminated food and tap water are considered.

Increased iodine requirements in infants, children suggest particular vulnerability to perchlorate: The World Health Organization (WHO) recommends that the average adult should consume 2 micrograms of iodine per kilogram of body weight per day to meet daily nutritional requirements. In contrast, WHO recommends that young children and infants ingest 3 and 7.5 times more iodine respectively per kilogram of body weight per day than non-pregnant adults (WHO 1998). This is because thyroid hormone production and turnover are greater in infants and children, compared with adults (Ginsberg et al 2007, Meikle 2007). High iodine requirements among infants and children may result in particular vulnerability to perchlorate related changes in thyroid hormone levels among these populations when compared with adults. This is because perchlorate interferes with iodine uptake by the thyroid gland, and since infants and children require more iodine that adults, any contaminant that disrupts this process may impact them more severely. This particular vulnerability is recognized by the National Academy of Sciences, which noted in a 2005 report that in "pregnant women, infants, and children, and people who have low iodide intake or pre-existing thyroid dysfunction, the dose [of perchlorate] required to cause a decrease in thyroid hormone production may be lower [than for non- pregnant adults]" (NAS 2005).

Studies reveal widespread perchlorate contamination of breast milk: In three recent studies from CDC and academic scientists, samples of human breast milk from different parts of the country were tested for perchlorate. Every single sample of breast milk in all three studies was positive for perchlorate (Kirk et al 2005, Kirk et al 2007, Pearce et al 2007). In addition, the average levels of perchlorate in breast milk in these studies would result in exposure above the agency's RfD for a significant numbers of breast-fed infants.

Further, in all three breast milk studies, a significant number of samples contained insufficient levels of iodine to meet the requirement of breast fed infants, meaning that not only would babies drinking this breast milk be exposed to hazardous levels of perchlorate by EPA's standards, but they would also be deficient in the iodine necessary to counteract the thyroid hormone lowering effects of the contaminant, thereby magnifying potential health effects of perchlorate in these infants.

While there is no question that perchlorate in both food and tap water contributes to breast milk contamination, minimizing perchlorate in tap water is an important overall way in which to decrease this contamination. There is presumably a relationship between the amount of perchlorate a woman consumes and the perchlorate concentration in her breast milk; decreasing her exposure by minimizing tap water contamination would most likely result in decreased perchlorate levels in her breast milk. In addition, those infants who are fed both breast milk and powdered formula have multiple sources of exposure from contaminated breast milk, formula, and tap water used to reconstitute the formula. For all of these reasons, setting an MCL for perchlorate of <1 ppb would present a meaningful opportunity to reduce breast milk contamination and decrease perchlorate exposure among infants.

Infants and children particularly vulnerable to toxic effects of perchlorate: Adequate circulating levels of thyroid hormones are critical to maintaining normal metabolism in adults, but are especially important for infants and children. Infancy and early childhood are times of rapid growth and brain development, and any abnormal decreases in thyroid hormone levels during these critical periods may lead to inhibition of these processes. Infants and children may suffer from stunted growth and delays in intellectual development if they have inadequate levels of thyroid hormones. These impacts on growth and brain development can be long-term and irreversible. These concerns recently prompted Dr. Melanie Marty, Chair of EPA's Children's Health Protection Advisory Committee (CHPAC) to state in a November 3rd, 2008 letter to the agency:

"The life-long consequences of impaired brain development are sufficient to merit setting a protective MCL for perchlorate (CHPAC 2008)."

Perchlorate exposures below RfD affect thyroid hormone levels: Lastly, EWG would like to address the agency's current RfD for perchlorate. On the last page of the notice, the agency states, "EPA agrees that additional important data have become available since the RfD was derived in 2005. However, EPA has evaluated the new data and has decided to make the regulatory determination based on the current RfD." EWG strongly disagrees with this finding and we urge EPA to revise the RfD to reflect the most current science. The current RfD was derived from the Greer study, which has been critiqued in the peer-reviewed literature and by a state regulatory agency, the Massachusetts Department of Environmental Protection.

A recent large-scale epidemiological study from CDC calls into question the actual safety of the agency's RfD (Blount et al 2006b). In September of 2006, CDC scientists published the first major epidemiological study using National Health and Nutrition Examination Survey (NHANES) data on the potential health impacts of chronic perchlorate exposure. Researchers found a statistically significant, dose-dependent association between perchlorate exposure and changes in thyroid hormone levels in all of the women in the study. In women with lower iodine levels (one third of American women), perchlorate exposure far below the EPA RfD was associated with significant changes in thyroid hormone levels. This is the first study to establish iodine insufficiency among women as a risk factor for perchlorate induced thyroid toxicity. This new discovery highlights a major deficiency in the Greer study; the iodine status of the 37 participants in that study is unknown.

In the Blount study, women were classified based on urinary iodine levels; those women with urinary iodine levels <100 ug/L had significant changes in both TSH and T4 associated with perchlorate exposures far below the current RfD. For a subset of women in the study with lower iodine levels [those with higher baseline thyroid stimulating hormone (TSH) values], exposure to perchlorate as low as five ppb in drinking water was associated with increases in TSH that fall into the range of a medical condition called subclinical hypothyroidism. While there is disagreement about whether this condition should be treated in non- pregnant women, there is consensus in the medical community that pregnant women who develop this condition should be treated with thyroid hormone in order to ensure normal brain development of their fetus.

The results of the Blount study call into question the safety of the RfD and raise the possibility that perchlorate exposures in infants and children may be exerting a far more significant clinical effect that previously believed. As mentioned above, infants and young children are routinely exposed to perchlorate concentrations close to the current RfD from formula, breast milk, and food exposure.

Even minimal drinking water contamination can lead to cumulative exposures that exceed the RfD among these vulnerable populations. The results from CDC's study, which did not include children under the age of 12, suggest that perchlorate exposures far below the current RfD may significantly affect thyroid hormone levels in adult women. If the results from the CDC study are extrapolated to vulnerable populations, millions of infants and children may be experiencing perchlorate-induced disruption in thyroid hormone levels during critical stages of brain development and growth at current levels of exposure, far below the current RfD.

Response: EPA acknowledges and thanks you for providing additional data related to perchlorate. EPA will continue to evaluate the available science related to perchlorate. On August 19, 2009, EPA published a Federal Register notice requesting supplemental public comments on its preliminary determination not to regulate perchlorate in drinking water (Federal Register Vol. 74, No. 159, p. 41883). In this August 19, 2009 Federal Register notice, EPA requested comments on additional interpretation of data on the level of human health concern, perchlorate frequency of occurrence in drinking water, and the opportunity for health risk reduction through a national primary drinking water standard, to help determine if it should be regulated. EPA considers both the extent of national occurrence and the severity of health effects for a contaminant, as well as other factors (e.g., sources of exposure), when deciding whether regulation presents a meaningful opportunity for health risk reduction. Therefore, the Agency considered national occurrence and the severity of health effects from perchlorate and concluded that regulation was warranted, so EPA has determined that perchlorate will be regulated.

Comment: 3). OIG presented a compelling argument that perchlorate regulation should not be based on risk assessment of perchlorate alone, but on an assessment of the complex mixture of naturally-occurring NIS stressors that includes perchlorate. Moreover, "lack of iodine in the diet (a.k.a. iodide deficiency)" is the most important of those NIS stressors (13).

Response: See response to comment ID 28529 under comment code 2500.

Comment: EPA must also consider other exposure pathways and additional contaminants in the environment that impact thyroid function when establishing the MCL. Studies of perchlorate levels in food, including breast milk, show that the population is exposed through multiple pathways in addition to contaminated drinking water. EPA should determine potential aggregate exposures based on a broad range of contamination levels, and not just the mean, which was the basis for current estimates.

While data have also demonstrated a particular threat to the significant number of individuals, especially women of child-bearing age who are iodide deficient, the current modeling does not include this threat. Given this widespread problem (CDC estimates up to 30% of women do not get sufficient dietary iodide), it is critical to take into consideration the potential for exposure to other thyroid- active agents. Consequently, EPA must consider the cumulative impact of perchlorate, other substances in the environment that inhibit the uptake of iodide by the thyroid, and inadequate supplies of iodide in American diets, all of which makes a stringent drinking water standard necessary to be truly health protective.

Comment: Comment No. 10

Section III.A. 4. Request for Comment on Alternative Approaches.

Page & Paragraph Page 41886

Comment We believe that at this time, PBPK modeling is necessary to be able to more fully consider sensitive subpopulations' exposure to chemicals that bind to the NIS receptor such as perchlorate, thiocyanate, and nitrate from dietary sources and the significance of low levels of perchlorate in drinking water. EPA should consider whether thiocyanate and nitrate may have a much greater impact than perchlorate for the most sensitive subpopulations with insufficient iodide and how best this can be resolved.

Consideration should also be given to the differences in the rate of excretion of thiocyanate and nitrate in human urine compared to perchlorate and the half- life of each (relative amount of time in the body from ingestion prior to excretion and the differences in the strength of iodide uptake inhibition).

Suggested Action, Revision and References (if necessary) We also recommend validation and/or comparison of the results of the current EPA revised PBPK model (2009) with biological fluid data derived that are available from perchlorate exposure studies. Studies include those recently published by the CDC and NIEHS (Blount et al., 2009) and the longitudinal epidemiologic study of pregnant women in Northern Chile (references provided below) as well as other scientifically sound human data. The CDC and NIEHS study reported not only new sensitive subpopulation-related perchlorate and iodide biological fluid data but they also compared thiocyanate and nitrate found in maternal and fetal compartments to levels found in other published studies. We believe that consideration of such data is consistent with EPA's statement made in the FR announcement that they will "...continue to evaluate any new perchlorate data to determine its relevance to the regulatory determination in accordance with the SDWA."

Response: See response to comment ID 28529 under comment code 2500. EPA concluded that the PBPK modeling analysis, in the context of the perchlorate regulatory determination, is useful in examining which life stages are most susceptible to the effects of perchlorate. For example, the model indicates that a fetus may be seven times more sensitive to the effects of perchlorate than a pregnant woman. The model also allows for the estimation of the concentration of perchlorate in breast milk (thus breast-fed infant exposure) at various maternal perchlorate exposure levels. However, because of the stated limitations, EPA has decided the model does not directly bear on the current decision regarding the need for a NPDWR for perchlorate.

Comment: 3) OTHER NIS INHIBITORS

Although the NAS committee members were aware of the significance of other NIS inhibitors and had access to the Tonaccera et al 2004 study, they were restricted by their charge to considering only perchlorate. All NIS inhibitors share the same mechanism of toxicity as perchlorate by blocking the uptake of iodide by the thyroid. The risk to public health is from the combined amount of NIS inhibition acting on the body from all three NIS inhibitors (thiocyanate, nitrate, and perchlorate). The combined total NIS inhibition load acting on the thyroid (not just perchlorate exposure) determines the total iodine uptake level and the subsequent potential for an adverse outcome. Adverse thyroidal effects of high concentrations of thiocyanate have been reported in numerous studies (Gibbs, 2006)

As noted in the OIG draft report, perchlorate, thiocyanate, nitrate and low iodine intake fit the criteria of a cumulative risk assessment. OIG reports that thiocyanate, nitrate, and iodine are found naturally in food and water sources, assuming that people are not exposed to any one of these chemicals alone, but in combination. Thus, the focus on one chemical does not in fact provide a scientifically accurate assessment of possible human health risk. The cumulative risk assessment approach provides the best opportunity to impact public health.

Comment: The 15 ppb drinking water level proposed under the October 2008 preliminary guidance is sufficiently protective as few drinking water systems were shown to exceed this level in the 2000-2001 sampling of water systems. Fewer systems are likely to even reach this level as states such as California and Massachusetts have since set more stringent drinking water levels of 6 ppb or below, and sources of potential contamination are being remediated. For these reasons, EPA has difficulty justifying that meaningful public health protection will result from regulation as the percentage of the public residing outside of states where regulations are already in place, and where perchlorate occurrence in drinking water supplies is at a meaningful level, is remarkably small. It appears that EPA has attempted to push the limit lower in an attempt to justify larger numbers of population affected in order to meet the SDWA criteria concerning exposure/occurrence. The Agency has not addressed in its analysis that the population of an area that may be impacted fails to differentiate that most adults and older children are not as sensitive to the effects of perchlorate as the fetus of a pregnant woman, the subpopulation identified by the NRC as being the most sensitive. Instead,

EPA has attempted to use the total number of population exposed by a water provider with perchlorate occurring in drinking water as being equally exposed and equally at risk. This assessment ignores that more targeted means of addressing potential sensitivities, or personal concerns, may be effected through the consumption of bottled water (a common practice that is not factored into EPA's analysis), or the provision of a diet with sufficient iodine to make a drinking water consumer less likely to be iodine deficient. Even with regulation, EPA's efforts do nothing to focus public health efforts on attaining iodine sufficiency and, therefore, miss the real public health threat.

Response: EPA disagrees. EPA is using a data driven approach considering the totality of the best available, peer reviewed data to develop an NPDWR that is protective of human health. EPA will consider the economic impacts of the proposed MCL in developing theNPDWR.

Comment: I believe the percentage of iodide deficient women several decades ago was possibly half what it is at the present. It seems likely that the media coverage of excess salt intake has caused many individuals to self medicate, avoid salt, and indirectly limit their iodide intake. This changes the size of the population at risk. Similar changes are possible in the amounts of thiocyanate and nitrate which people ingest. The EPA provides the following info on p.41892 in its FR solicitation for comments:

An additional key scientific issue was raised by EPA's OIG in the report released for public comment "OIG Scientific Analysis of Perchlorate (External Review Draft)" (EPA, 2008g). The report states,

The OIG [Office of Inspector General] Analysis concludes that a single chemical risk assessment of perchlorate is not sufficient to assess and characterize the combined human health risk from all four NIS stressors, (i.e., thiocyanate, nitrate, perchlorate and lack of iodide) and that * * * Only a cumulative risk assessment can fully characterize the nature and sources of risk affecting this public health issue. Furthermore, a cumulative risk assessment allows an informed environmental decision to be made on how to mitigate the risk effectively.

The report goes on to say, Potentially lowering the perchlorate drinking water limit from 24.5 ppb to 6 ppb does not provide a meaningful opportunity to lower the public's risk. By contrast, addressing moderate and mild iodide deficiency occurring in about 29% of the U.S. pregnant and nursing population appears to be the most effective approach of increasing TIU [total iodide uptake] to healthy levels during pregnancy and nursing, thereby reducing the frequency and severity of permanent mental deficits in children.

I concur completely, and endorse this position. Additionally, the fact that iodide deficiency, thiocyanate, and nitrate content in the population at risk are all changing quantities over time make it inappropriate to set a hard and fast MCL that is scientifically sound. There is nothing wrong with changing an MCL when new information comes to light regarding the action of that contaminant on

the population at risk. It is another matter, however, when the population at risk changes over time and should in prudence be mitigating that risk by other health means.

Response: EPA has determined that a NPDWR for perchlorate is warranted. See response to comment ID 28529 under comment code 2500

Comment: The Safe Drinking Water Act (SDWA) specifically mandates that the EPA use the "best available peer reviewed science" for supporting sound and technical regulatory determinations. However, to date the EPA seemingly has not considered the valuable epidemiological data available in peer-reviewed literature. The epidemiological studies and other human studies, most notably Greer 2002 (Greer, Goodman et al. 2002), take into account the relative source contribution (RSC). By utilizing the wealth of data provided in these studies, the EPA would no longer need to consider Relative Source Contribution (RSC) when health effects, or no observed adverse effects levels (NOAELs), are calculated using these and other human-exposure studies. While a potential criticism lies in the theoretical absence of specific subjects with iodine deficiencies, we agree with the EPA's Inspector General in stating that regulatory action under the SDWA is not the appropriate or effective way to address the overarching public health issue - iodide deficiency. For these reasons alone, we believe that epidemiological data available for exposure to perchlorate through drinking water should be evaluated before turning to the more nebulous PBPK modeling.

Response: See response to comment ID 28718 under comment code 2600
EPA concluded that the PBPK modeling analysis, in the context of the perchlorate regulatory determination, is useful in examining which life stages are most susceptible to the effects of perchlorate. For example, the model indicates that a fetus may be seven times more sensitive to the effects of perchlorate than a pregnant woman. The model also allows for the estimation of the concentration of perchlorate in breast milk (thus breast-fed infant exposure) at various maternal perchlorate exposure levels. However, because of the stated limitations, EPA has decided the model does not directly bear on the current decision regarding the need for a NPDWR for perchlorate

Supplemental comments regarding the fundamentally different outcomes between Greer, et al, 2002 and the Blount, et al, 2006 studies on low dose effects of perchlorate

By: Herwig Opdebeeck, SM, Opdebeeck Consulting[FN1: Mr. Opdebeeck can be reached at +41 79 658 7979, or h.opdebeeck@opdebeeck.ch.], October 8th, 2009

Executive summary

In the Blount study, an association between perchlorate levels and TSH was found at levels four orders of magnitude lower than has been found in previous studies. However, this result does not appear to represent a causal relationship between perchlorate and TSH, due to the inconsistent results exhibited by perchlorate and the other goitrogens, thiocyanate and nitrate, within the same study. To our knowledge, no in depth study has been published which explains these inconsistencies exhibited by the Blount study in a manner that would continue to support its conclusions and allow the study to be used as the basis for regulation of perchlorate. Instead, our analysis of the other substances not controlled for in this cross sectional study supports the conclusion that the inconsistent and unexpected results of the Blount study are the result of causal associations between these other substances and thyroid hormone levels.

Even though only a few of the many substances with the capability of affecting thyroid function were surveyed in the same NHANES database on which the Blount study was based, we found several that showed the same association with TSH. Added to the fact that the association of those substances with thyroid hormone was at levels that are known to cause those effects and not at levels four orders of magnitude lower as was the case for the perchlorate association, it is apparent that the association with thyroid hormone found in the Blount study is not due to perchlorate but due to a pool of goitrogenic substances of which the perchlorate background is only a marker.

In conclusion, not only didn't the Blount study show an upstream iodine inhibition (i.e., it didn't show a relationship between iodine and THs), but additionally perchlorate, which only represents 1% of the NIS goitrogen load, and all three NIS goitrogens seem to have been fully compensated by iodine - explaining the non-relationship of iodine with TH. For the NIS goitrogen perchlorate, it should also be noted that at background levels, it is a strong predictor of environmental iodine background levels. Additionally, goitrogenic compounds shown to have a direct effect on TH levels and at levels know to cause such effects, were found to be associated with TSH as well, without exhibiting the inconsistencies found in the Blount study. Finally, a plausible link can be found between those compounds and perchlorate, a marker for the goitrogenic pool through the chlorine link.

Acronyms BW: Body weight of an adult (70Kg) DW: Drinking water DWL: Daily drinking water consumption in litres (2 L) DBP: Disinfection by-products EGP: Environmental goitrogenic pool (see GC) MCL: Maximum contaminant level NAS: National Academy of Sciences =NRC NIS: Sodium iodine symporter NOEL: Non observed effect level NRC=National Research Council = NAS DWS: Drinking water standard GC: goitrogenic contaminants (substances that inhibit iodine uptake and therefore could affect TH levels or substances such as PCBs that directly affect TH levels) OIG: EPA's Office of Inspection General PHG: Public health goal RfD: Reference dose sum23PCB= the sum of the concentrations of 23 PCBs in the NHANES 2001-2002 dataset. TGL: Total (NIS) goitrogen load TH: thyroid hormone UF: Uncertainty factor UPEC (or UTGL): Urinary perchlorate equivalent concentration expressed in PEC: [Perchlorate] + [nitrate/150] + [thiocyanate/8.8] with concentrations in weight.

Response: EPA will consider the totality of the best available, peer reviewed science in developing the NPDWR for perchlorate. Data will be evaluated using a weight of evidence approach, considering each study in the context of the entire database.

Comment: Summary

Preliminary note: When expressing a relationship between variables in a cross- sectional study we sometimes use the term "predictor of "(term used in Blount et al. study) which has the same meaning as "associated with" or "related with".

We statistically analyzed some of the other substances contained in the same NHANES 2001-2002 data on which the Blount et al. study was based, and found similar statistically significant associations between some of those substances and TSH. We did not look for associations with T4 since, after adjusting for creatinine, the association between perchlorate and T4 disappeared for the pertinent subpopulation, women of childbearing age with insufficient levels of iodine[FN4: Lamm SH, Hollowell JG, Engel A, Chen R (2007). Perchlorate, thyroxine, and low urine iodine association not seen with low creatinine- adjusted urine iodine among women of childbearing age. Thyroid 17 (s1):S-51].

Indeed there exist many other goitrogenic substances that have a different mode of action not related to iodine uptake inhibition. The Blount study is about possible effects on THs of substances present in the population sample. Therefore, all known substances that affect TH levels, all goitrogenic contaminants (GC), should have been statistically tested and controlled for as well and not only those that act through the same mechanism as perchlorate. Since iodine levels are probably not relevant to explain the Blount TH level changes as they are not associated with TH levels in the same population sample, we should, in order to find a cause, not look with priority for goitrogens that affect NIS function (i.e. uptake of iodine) but GCs that directly affect TH levels.

EPA's current RfD for perchlorate is based on perchlorate's ability to competitively inhibit the thyroid gland's uptake of iodide. It is, therefore, surprising that EPA does not raise this issue when commenting on the Blount study, but instead limits itself to discussing nitrate and thiocyanate. If the Blount et al. study was focused on the iodine uptake inhibition effect, then this would have been justified. But it was not. Instead, it was about the downstream effect, the effect on TH. There are indeed hundreds of environmental contaminants, natural and synthetic, that directly affect thyroid hormone levels and which we can call the environmental goitrogenic pool (EGP). Many have not been studied and none were tested and controlled for in the Blount study, even though the levels of some were available in the NHANES 2001-2002 database of the same population for which the perchlorate - TH relationship was found. We found that the relationship between some of those substances i.e., (certain organo- halogens) with TH was similar with the one of perchlorate.

We found that the sum of the concentrations of 23 PCBs from the NHANES 2001-2002 database was a predictor of TSH for the same Blount total population ($p = 0.0037$). For women, we found that sum23PCB was a significant predictor of TSH ($p=0.0027$) and that there was no iodine interaction, or in other words the relationship of sum23PCB was the same for all levels of iodine, or

the PCB-TSH relationship was not influenced by the iodine level. For men sum23PCB was not a significant predictor of TSH.

For the total population sample, we also found that pp-DDE was a significant predictor of TSH (p=0.0185). For women, but not for men, pp-DDE was a significant predictor of TSH (p=0.0040) and again without iodine interaction which is coherent.

We suggest that the main link between perchlorate and those goitrogenic contaminants that directly affect TH levels is the element chlorine via chlorophenols, some of which originate in disinfection by-products (DBP) and many other processes where chlorine derivates are involved. The threshold effect level on THs of organohalogens such as PCBs and other dioxin- like mostly chlorine based organic substances has been found to be in the range of 0.1 to 10 ug /l serum depending on the substance. The levels of those substances found in NHANES 2001-2002 is in this range and, as mentioned, a relationship between some of these substances and THs was found as well. This is in stark contrast with the four orders of magnitude difference between the effect level of perchlorate on THs known from the body of the literature and the perchlorate levels that were related with THs found in the Blount study.

Opting for the broad picture and looking for the most likely cause of these effects produced leads which, when compared to the data, points toward a vast pool of goitrogenic compounds, natural and synthetic as the source of impacts to TH. Of these, the low level perchlorate background is only a marker, most probably through the chlorine link, rather than the cause.

In order to answer the question presented in the heading, we propose the following steps:

2.1. Opting for the broad picture

We hear a lot about the value of holistic approaches and cumulative risk assessment in documents such as: US Environmental Protection Agency (US EPA), Framework for Cumulative Risk Assessment, EPA/630/P-02/001F, National Center for Environmental Assessment, Office of Research and Development, Washington, DC, 2003a, available at http://cfpub.epa.gov/ncea/cfm/recordisplay.cfm?deid=54944.

This is an excellent opportunity to put it in practice. EPA's OIG in its December, 2008 study on perchlorate[FN5: Office of Inspector General Scientific Analysis of Perchlorate ,Assignment No. 2008-0010, December 30, 2008.] certainly took an important step in that direction, and we agree that a cumulative approach is critical to the accurate evaluation of perchlorate's risks, and should be the underpinning for any regulatory decision making regarding perchlorate.

2.2. Looking for the "culprit(s)" where they are most likely to be

There exist many other goitrogenic substances which lead to TH level change, that have a different mode of action (not related to iodine uptake inhibition) than the traditional NIS affecting goitrogens. The Blount study is about possible effects on THs of background contaminants. Therefore, all known contaminants that affect TH levels should have been statistically tested and controlled for as well and not only those that act through the same mechanism as perchlorate. Since background iodine levels are probably not relevant to explain the Blount TH level changes, as they are not related to TH levels in the same population sample[FN6: 1. Charnley G, Perchlorate:

Overview of Risks and Regulation. Food and Chemical Toxicology, 2008. 2. Soldin OP, Tractenberg RE, Pezzullo JC. Do thyroxine and thyroid-stimulating hormone levels reflect urinary iodine concentrations? Therapeutic Drug Monitoring. 2005, 27: 178-185.], we should not look primarily at goitrogens that affect the uptake of iodine (and therefore have only a potentially indirect effect on TH levels) but goitrogenic contaminants (GCs) that directly affect TH levels.

EPA's current RfD for perchlorate is based on perchlorate's ability to competitively inhibit the thyroid gland's uptake of iodide. Therefore, it is surprising that EPA does not raise this issue when commenting on the Blount study, but limits itself to mentioning nitrate and thiocyanate. If the Blount study had been about iodine uptake inhibition effect then this would have been justified. But it was not. Instead, it was about the downstream effect - i.e., the effect on TH levels. However, in the Blount study it was assumed that iodine uptake inhibition was the upstream effect, so much so that the study population had been split into 2 groups -- iodine deficient and iodine sufficient. This only created additional inconsistencies, as it exposed additional "unexpected" relationships which should have been seen as a warning that something was amiss.

Limiting the whole issue to iodine uptake inhibitors, of course, made the study much simpler to manage, but was not the right way to draw plausible conclusions about cause.

2.3. Looking for a lead

We quote from the January 2008 Thyroid journal:

"Toxicological models and limited epidemiological studies have indicated that many organohalogen aromatic compounds, including dioxins, polychlorinated biphenyls (PCBs), and polybrominated diphenyl ethers (PBDEs), may be classified as "endocrine disruptors, as they have the potential to alter normal thyroid function."

"Because environmental exposures rarely occur singly, it is often difficult to disentangle a single exposure from other co-occurring environmental exposures and conditions that may confer risks upon children. Therefore, there is often the potential for confounding, in which both the exposure and the outcome under investigation are related to a third factor that may distort the observed exposure-disease relationship."

"In epidemiologic studies, it is critically important to identify, measure, and control for such confounders."

Therefore, other substances could have caused the TH changes.

While NHANES 2001-2002 TH levels, as mentioned before, do not reflect urinary iodine concentrations, serum PCBs, p,p'-DDE and HCB background levels predict TH levels[FN7: John D. Meeker, Larisa Altshul, Russ Hauser. Serum PCBs, p,p'-DDE and HCB predict Thyroid Hormone Levels in Men. Environ Res. 2007 June; 104(2): 296-304.] and some do so in NHANES 1999-2002 survey population as well[FN8: Mary E. Turyk, Henry A. Anderson, Victoria W. Persky. Relationships of Thyroid Hormones with Polychlorinated Biphenyls, Dioxins, Furans, and DDE in Adults. Environmental Health Perspectives. August 2007,Volume 115, Number 8.]. However the background levels of only few such substances have been measured and tested against TH levels.

Yet in the NHANES 2001-2002 survey, a few of those substances have indeed been measured and therefore can be tested for associations with other contaminants in the same survey.

2.4. Focusing initially on those type of substances that are already in the NHANES 2001-2002 survey of the same population surveyed by Blount

Since organochlorides such as PCBs, DDE and other organochlorides that have been shown to directly affect TH levels are included in that survey, it should have been obvious that those substances should have been considered in the Blount study in the first place -- or at least controlled for before any other relationship was suggested.

2.5. Comparing the data on the different "suspects" comprised in the NHANES dataset

Preliminary note: We did not look for associations with T4 since, after adjusting for creatinine, the association between perchlorate and T4 disappeared for the pertinent subpopulation, iodine-insufficient (UI<100 ug/L) women of childbearing age (see ref. 4).

(a) Perchlorate versus TSH for the total (male plus female) population

The Blount study did not show that perchlorate was a significant predictor[FN9: In this paper we use the same term "predictor of" as used by Blount et al. which means the same as "associated with" and "related with", terms we also use in this paper.] of serum TSH. ($p>0.05$) for the total population.

(b) Sum of some PCBs versus TSH PCBs are one group out of a multitude of other substances that act on thyroid function (see details in Appendix 2).

We found that the sum of the concentrations of 23 PCBs from the NHANES 2001-2002 database was a predictor of TSH for the same total population ($p= 0.0037$)

(c) Perchlorate and PCBs versus TSH controlled for gender

For women (all), Blount's data indicates that perchlorate was a significant predictor of TSH (note that Blount did not publish a p value, but we found $p= 0.0153$ and $R2=0.006$) and no iodine interaction which is consistent if the predictor is not the cause.

For women < 100 ug/l UI, perchlorate was a significant predictor of TSH ($p= 0.001$).

For women > 100 ug/l UI, perchlorate was a significant predictor of TSH ($p= 0.0249$) which is inconsistent if the predictor (perchlorate) is the cause and consistent if the predictor is not the cause.

For men, Blount found that perchlorate was not a significant predictor of TSH. Further, as mentioned in our previous comment (EPA-HQ-OW-2009-0297-0227), we found that in the Blount study there was a strong relationship between iodine and perchlorate ($p<0.0001$ and $R2= 0.36$). This is an additional indication that perchlorate could not have affected TSH, in addition to the other main arguments: i) an upstream iodine inhibition was not shown; ii) there was no relationship between iodine and THs; iii) perchlorate only represents 1% of total NIS related goitrogen load and; iv) perchlorate levels seem to have been compensated by iodine. In fact, iodine levels not only seem

to fully compensate for perchlorate levels but also for the levels of the other two NIS goitrogens, nitrate and thiocyanate or conversely, low levels of iodine were compensated for by low levels of goitrogen load (see Appendix 3).

For women, we found that sum23PCB was a significant predictor of TSH (p=0.0027) and that there was no iodine interaction, or in other words the relationship of sum23PCB was the same for all levels of iodine or the PCB-TSH relationship was not influenced by the iodine level. For men sum23PCB was not a significant predictor of TSH.

(d) pp- DDE (dichlorodiphenyldichloroethylene) as a predictor for TSH In Appendix 2, we demonstrate in detail the relationship between pp-DDE, another dioxin-like organochlorinated compound found in the NHANES 2001-2002 dataset, and TSH. The associations compared with those of perchlorate are summarized as follows:

* For the total population sample, our study found that pp-DDE was a significant predictor of TSH (p=0.0185) * For women, but not for men, pp- DDE was a significant predictor of TSH (p= 0.0040). * Further we did some additional analyses and found the following additional relationships or outcomes when investigating the association between pp-DDE and TSH: 1. There was no interaction between pp-DDE and iodine and gender, which is consistent (as it is expected in the case of a non-NIS goitrogen) 2. There was no interaction between gender and iodine. 3. There was no interaction between iodine and pp-DDE, which is consistent (as it is expected in the case of a non-NIS goitrogen) 4. There was no effect of iodine on TSH (see ref. 6), which is consistent (expected : see ref. 6) 5. After correcting for pp-DDE, an increase of perchlorate was associated with an increase of TSH, only for females (p=0.0003). 6. After correcting for perchlorate, an increase of pp-DDE was associated with an increase of TSH, only for women (p=0.004).

Conclusion: Only one single goitrogenic organochlorinated substance directly affecting the level of THs is already associated with TSH at environmental background concentrations, and all other outcomes are consistent with expected results.

2.6. Looking for links between perchlorate and the members of the goitrogenous pool

To further support the absence of a causal relationship between perchlorate with TH, ideally a second relationship -- a relationship between perchlorate and those organo- halogens that directly affect TH levels -- should be found. Although it is difficult to statistically demonstrate this relationship, due to the presence of other confounding environmental GCs, the most obvious and most widely spread common link is chlorine via chlorophenols. For additional explanation, see Appendix 1.

Following a summary of Appendix 1: -DBP road 1: From bleach/Cl2/Cl-/chloramine->-> ClO3 -> ClO4- -DBP road 2 (in presence of organic (C) material): From bleach/ Cl2/Cl-/ chloramine->-> phenols ->-> organochlorides / dioxins with DBP= Disinfection by- products

Since organo-chlorinated compounds are ubiquitous, and since we find at least 1/3 of the total dietary perchlorate where we find organo-chlorinated compounds (see Appendix 1), and since many of those have been shown to affect TH levels, it is to be expected that low levels of perchlorate are associated with TH levels as found in the Blount study. This association, however, does not demonstrate causation, as Blount suggests. Given the complicated and overlapping effect of many

substances on TH levels, assigning cause to this association between perchlorate and TH levels defies logic and does not explain the inconsistencies revealed within the study itself.

Instead, perchlorate appears to be a marker, a "witness" of the presence of ubiquitous goitrogenic contamination caused by the net effect of hundreds of substances (See also section 2.8). Instead of representing the cause of the impact, perchlorate is correlated to the presence of other ubiquitous goitrogenic substances which contribute to the overall impact on TH. This alternative explanation makes logical sense, and explains the contradictions and inconsistencies regarding the other NIS goitrogens found in the Blount study.

2.7. Finally, the "alibi": background levels found compared with known effect levels

The known threshold effect level on THs of organohalogens such as PCBs and other dioxin-like substances has been found to be in the range of 0.1 to 10 ug /l serum depending on the substance[FN10: Lesa L. Aylward, Julie E. Goodman, Gail Charnley, Lorenz R. Rhomberg. A Margin-of-Exposure Approach to Assessment of Noncancer Risks of Dioxins Based on Human Exposure and Response Data. Environmental Health Perspectives. October 2008. Volume 116, Number 10.][FN11: Lawrence M. Schell, Mia V. Gallo, Melinda Denham, Julia Ravenscroft, Anthony P. DeCaprio, David O. Carpenter. Relationship of Thyroid Hormone Levels to Levels of Polychlorinated Biphenyls, Lead, p,p'- DDE, and Other Toxicants in Akwesasne Mohawk Youth. Environmental Health Perspectives. June 2008, Volume 116, Number 6.] [FN12: Johan Maervoet, Griet Vermeir, Adrian Covaci, Nicolas Van Larebeke, Gudrun Koppen, Greet Schoeters, Vera Nelen, Willy Baeyens, Paul Schepens, Maria K. Viaene. Association of Thyroid Hormone Concentrations with Levels of Organochlorine Compounds in Cord Blood of Neonates. Environmental Health Perspectives. December 2007, Volume 115, Number 12.][FN13: Jonathan Chevrier, Brenda Eskenazi, Asa Bradman, Laura Fenster, Dana B. Barr. Associations between Prenatal Exposure to Polychlorinated Biphenyls and Neonatal Thyroid-Stimulating Hormone Levels in a Mexican-American Population, Salinas Valley, California. Environmental Health Perspectives. October 2007. Volume 115, Number 10.][FN14: Mary E. Turyk, Henry A. Anderson, Victoria W. Persky. Relationships of Thyroid Hormones with Polychlorinated Biphenyls, Dioxins, Furans, and DDE in Adults. Environmental Health Perspectives. August 2007, Volume 115, Number 8][FN15: June-Soo Park, Linda Linderholm, M. Judith Charles, Maria Athanasiadou, Jan Petrik, Anton Kocan, Beata Drobna, Tomas Trnovec, Åke Bergman, Irva Hertz- Picciotto. Polychlorinated Biphenyls and Their Hydroxylated Metabolites (OH- PCBs) in Pregnant Women from Eastern Slovakia. Environmental Health Perspectives Volume. January 2007, 115, Number 1.].

The background levels of those substances found in NHANES 2001-2002 are in this range and, as mentioned, a relationship between some with THs was also found in other NHANES data based studies (see ref. 6; ref.7-11 based on other datasets, show similar levels). This is in stark contrast to the four orders of magnitude difference between the effect level of perchlorate on THs known from the body of the literature and the perchlorate levels that were related to THs found in the Blount study.

These contaminants appear to be part of a wider ubiquitous contaminant pool, natural and manmade, in which there are all kind of GCs acting with all kind of mechanisms that influence TH levels and thyroid function. Most seem to be linked, but additional study would be required to fully understand their complex relationships with one another and with TH. For more information about relationships between GCs, see Appendix 2.

Conclusion

Suggesting that a downstream effect (TH level changes) is caused by a substance (perchlorate) without controlling for other relevant substances and at the same time neglecting to check whether that same substance has a link with a known upstream effect (iodine uptake inhibition) is not the basis of sound science. On the other hand, looking for the most likely causes of an effect (rather than a results-oriented approach seeking only to demonstrate a connection between perchlorate and TH) should produce more plausible leads. When comparing the data and the circumstantial evidence, those leads point towards a vast pool of goitrogenic compounds, both natural and synthetic, of which the perchlorate background only appears to be a marker most probably through the chlorine link.

Response: See response to comment ID 28715 under comment 2600. See also response to comment IDs 28529 and 28551 under comment code 2500. EPA is aware of the occurrence of perchlorate in some sources of hypochlorite/hypochlorous acid.

Comment: Appendix 2

The further development of the possible link perchlorate--organohalogens--TH

* Starting from an example: pp-DDE (dichlorodiphenyldichloroethylene) is a chlorinated pesticide while on the other side bromides are soil disinfectants that form organobromides which are goitrogenic substances[FN19: Johan Maervoet, Griet Vermeir, Adrian Covaci, Nicolas Van Larebeke, Gudrun Koppen, Greet Schoeters, Vera Nelen, Willy Baeyens, Paul Schepens, Maria K. Viaene. Association of Thyroid Hormone Concentrations with Levels of Organochlorine Compounds in Cord Blood of Neonates. Environmental Health Perspectives. December 2007, Volume 115, Number 12.]. So, both of those persistent organohalogens are often found together.

* Further, when bromine (a water disinfectant just as chlorine) and chlorine are involved, halogenated furanones can be produced by the reaction of naturally occurring organic matter and bromide with the disinfectant chlorine and chloramine. Research on their concentrations in drinking water is at an early stage and they are not regulated by EPA:
http://pubs.acs.org/cen/news/86/i13/8613news7.html

[Clarification: A furanone is a furan where the H is substituted with Cl, becoming polychlorinated furanones or polychlorinated dibenzofuranones. A furan is short for dibenzofuran; a chlorinated dibenzofuran is a PCB with a furan ring in the middle].

* This shows their common link with PCBs. Therefore, the halogen bromine can join the second pathway for chlorine: From bleach/Cl2/ Cl2/Cl-/chloramine, bromides ->-> furanones or phenols

->-> organohalogens /Dioxins. Thus all those persistent GCs are mostly related qualitatively and quantitatively with each other and apparently related with perchlorate.

* Associations between NHANES 2001-2002 data for pp-DDE versus TSH and perchlorate versus TSH illustrate the following: - Association between pp-DDE and TSH, total population: significant (p=0.0185) - Association between perchlorate and TSH, total population: not significant (p> 0.05). - Association between pp-DDE and TSH, women: significant (p= 0.0040) - Association between perchlorate and TSH: women < 100 ug UI, significant (p= 0.001) - Association between perchlorate and TSH: women > 100 ug UI, significant (p= 0.0249).

Conclusion: pp-DDE and other organo-halogens all seem to be related to each other and with perchlorate within the goitrogenic pool.

Further, we performed some additional analyses on pp-DDE and found the following additional relationships or outcomes when investigating the association between pp-DDE and TSH: 1. There was no interaction between pp-DDE and iodine and gender, which is consistent as it is expected in the case of a non-NIS goitrogen 2. There was no interaction between gender and iodine 3. There was no interaction between iodine and pp-DDE, which is consistent as it is expected in the case of a non-NIS goitrogen 4. There was no effect of iodine on TSH, which is consistent as it is expected (see ref. 6). 5. After correcting for pp-DDE, an increase of perchlorate was associated with an increase of TSH, only for females (p=0.0003). 6. After correcting for perchlorate, an increase of pp-DDE was associated with an increase of TSH, only for women (p=0.004).

Conclusion: The relation of those organohalogens with TSH seem to be consistent with an effect not depending on iodine levels, contrary to the perchlorate and other NIS goitrogen relations with TSH in the Blount study which are inconsistent not only with an iodine dependent effect but also show an inconsistent effect between each other.

* Some components of this goitrogenic contaminant pool have a stimulatory or agonistic effect, others an inhibitory or antagonistic effect[FN20: Cornelia Schmutzler, Inka Gotthardt, Peter J. Hofmann, Branislav Radovic, Gabor Kovacs, Luise Stemmler, Inga Nobis, Anja Bacinski, Birgit Mentrup, Petra Ambrugger, Annette Gruters, Ludwik K. Malendowicz, Julie Christoffel, Hubertus Jarry, Dana Seidlova-Wuttke, Wolfgang Wuttke, Josef Kohrle. Endocrine Disruptors and the Thyroid Gland-A Combined in Vitro and in Vivo Analysis of Potential New Biomarkers. Environmental Health Perspectives. December 2007, Volume 115, Number S-1.][FN21: http://www.ourstolenfuture.org/Basics/chemlist.htm]. Some do not have any effect at all at environmental doses. This may explain why in cross sectional studies as those based on the NHANES data base the effect of the sum of some PCBs apparently is not always greater than each individual effect as would be expected[FN22: Kevin M Crofton, Elena S Craft, Joan M Hedge, Chris Gennings, Jane E Simmons, Richard A Carchman, W Hans Carter, Jr., Michael J Devito. Thyroid-hormone-disrupting chemicals: evidence for dose-dependent additivity or synergism. Neurotoxicology Division, National Health and Environmental Effects Research Laboratory, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, North Carolina, USA. Environ Health Perspect. 2005 Nov ;113 (11):1549-54 16263510 (P,S,G,E,B).] as each individual PCB on itself can be linked to other non identified and quantified goitrogens i.e. (once again) not controlled for covariates with opposite effects.

* As mentioned, there already exist 209 known congeners of PCBs alone. They vary based on the number and positions of chlorine atoms but also on their effect (strength and direction). Many have not even been studied on their goitrogenic effect. The fact that the few that were studied, here and in other studies, were found to be predictors of TSH levels is so much the more remarkable.

* Even different groups of chemicals with different mechanisms could have synergetic or antagonistic effects[FN23: Andreas Kortenkamp. Ten Years of Mixing Cocktails: A Review of Combination Effects of Endocrine-Disrupting Chemicals. Environmental Health Perspectives, December 2007, Volume 115, Number S-1.].

* Others may be linked to each other in certain environments and not in others. For example Polychlorinated Biphenyls (PCBs) and Polybrominated Diphenyl Ethers (PBDEs) --both also called polyhalogenated phenolic compounds-- may have a cumulative effect where bromine and chlorine based disinfectants are used (for example for swimming pools) and end up as DBPs (disinfection by-products) in drinking water after having gone thru the purification plant. This link could not exist in places where one of both is not used.

* Other goitrogenic phenols, such as Bisphenol A, linked itself to polyvinylchloride (PVC) such as used in waterpipes, may be linked to this chloride and halogen pool.

* On the other side completely different types of GCs, even natural ones, could be linked indirectly to the pool as well: for example organohalogen based pesticides may be present in very low amounts in soybeans but the goitrogenic effect could instead be primarily due to the isoflavones naturally present in soymilk[FN24: Daniel R. Doerge, Daniel M. Sheehan. Goitrogenic and Estrogenic Activity of Soy Isoflavones. Environmental Health Perspectives Supplements. June 2002, Volume 110, Number S3.] or the thiocyanates present in rape or broccoli or other natural goitrogens such as genistein, resveratrol, silymarin, linuron[FN25: Environmental Protection Agency, EPA/600/P-03/002F).An Inventory of Sources and Environmental Releases of Dioxin-Like Compounds in the United States for the Years 1987, 1995 and 2000. Federal Register: December 1, 2006 (Volume 71, Number 231)] Page 69564-69565] Health Perspectives Supplements. June 2002, Volume 110, Number S3.]

* Also fluorine is considered a goitrogen[FN26: Fluoride in Drinking Water: A Scientific Review of EPA's Standards (NAS, 2006) http://www.iicph.org/docs/water- reg-20060830.htmhttp:// www.pubmedcentral.nih.gov/articlerender.fcgi?artid=476957]. So, adding fluorine in salt for dental purposes could partially neutralise the effect of added iodine. Adding fluorine, another halogen, in drinking water, which is also common, would then on itself be linked to perchlorate and the organohalogen DBPs.

* Further fluorine is a major constituent of phosphate fertilizers[FN27: http://fluoridealert.org/phosphate/overview.htm#2] and is taken up by the crop so it could, just as the goitrogenic pesticides and isoflavones, be part of the goitrogenic pool as well. Also iodine itself, the fourth halogen, is used as a disinfectant.

* Other factors, even the most unexpected (birth delivery mode) may confound the effects[FN28: Julie B. Herbstman, Andreas Sjodin, Benjamin J. Apelberg, Frank R. Witter, Rolf U. Halden, Donald G. Patterson Jr., Susan R. Panny, Larry L. Needham, and Lynn R. Goldman. Birth Delivery Mode Modifies the Associations between Prenatal Polychlorinated Biphenyl (PCB) and Polybrominated

Diphenyl Ether (PBDE) and Neonatal Thyroid Hormone Levels. Environmental Health Perspectives. October 2008, Volume 116, Number 10.].

* And finally the fact that "The R2 value of 0.061 reported by Blount et al. (2006a) for the association between TSH, perchlorate, and other significant covariates for lower-iodine women indicates that perchlorate accounts for only about 1% of the variation seen for TSH in that population"(quote extracted from ref.6.1) and that therefore about 99% is related directly to goitrogenic compounds once again strongly supports the role of perchlorate as a marker only and not a cause.

Comment: Appendix 3

Based on the principle of competitive uptake inhibition, it is impossible that perchlorate would have caused the TH changes found in the Blount et al, 2006 study

According to Tonacchera et al., Thyroid, 2004[FN29: Office of Inspector General Scientific Analysis of Perchlorate ,Assignment No. 2008-0010, December 30, 2008]

RAIU= 1.22 / (1.22 +PEC)

Where PEC =serum perchlorate equivalent concentration = [ClO4_] + [SCN_] / 15 + [I_] / 30 + [NO3_] / 240 = serum perchlorate + thiocyanate/15+ iodine /30 + nitrate concentration/240 and RAIU = Radioactive Iodine Uptake.

All concentrations are in umol.

The model is only valid for this specific lab trial set-up as described in Tonacchera et al., 2004 but has been generally accepted.

Assume that PEC A is a serum perchlorate equivalent concentration equal to A and PEC B is a serum perchlorate concentration equal to B.

From the above equation it follows that if PEC A is < PEC B the RAIU, which is the incremental iodine uptake, is larger for PEC A than for PEC B.

This then also means that, if there is no iodine inhibition for a certain level B of PEC in human serum, there will not be any iodine uptake inhibition for a level A of PEC in human serum either, if PEC A

(Note that PEC includes here the iodine level as iodine itself is an iodine uptake inhibitor. Indeed the more iodine present the more the uptake of the added (incremental) dose of iodine (marked here with radioactive iodine) will be inhibited and therefore the less (radioactive) iodine of the dose will be taken up).

Further, since we assume steady state (see note below), perchlorate, SCN, iodine and nitrate urinary levels are proportional to perchlorate, SCN, iodine and nitrate effective serum levels or in other words if PEC is, for example, double in serum of person B compared to PEC in serum of person A (ceteris paribus) we can assume that urinary PEC of person B will be double the urinary PEC of person A and vice-versa.

Note: We quote: "In all risk assessments on perchlorate iodine uptake inhibition "The central assumption is that the amount of perchlorate excreted per day equals the amount ingested in the bio-monitored individuals. This is true if these individuals are near or at steady state."(See: Evaluation of the U.S. EPA/OSWER Preliminary Remediation Goal for Perchlorate in Groundwater: Focus on Exposure to Nursing Infants ,Gary L. Ginsberg,1 Dale B. Hattis,2 R. Thomas Zoeller,3 and Deborah C. Rice.(ehp, Dec. 2006).

If perchlorate risk assessments are based on this assumption there is no reason why the same assumption could not be adopted here.

Also we can say that the segment of the general US population with an average of around 200 ug/l urinary iodine, which is well above the minimum WHO (World Health Organization) recommended level of 100 ug/l UI is on average not exposed to any iodine uptake inhibition and to such a level of inhibition as to cause TH (Thyroid Hormone) changes.

Hence, if using the Tonacchera RAIU equation but with urinary PEC instead, the segment of the US population with an average of 200 ug/l U iodine and with an average U PEC B has no overall iodine uptake inhibition, then we can deduct that the segment of the US population with for example an average of 30ug/l U iodine (thus iodine level B>A) but with a PEC A < PEC B and therefore a larger incremental uptake of (radioactive) iodine, does not have any iodine uptake inhibition as well.

We found that U PEC (as defined above) of the 1/8 segment of NHANES 2001-2002 female population with the average of 228 ug/l UI was higher than the U PEC of the 1/8 segment of NHANES 2001-2002 female population with the lowest average of 31ug/l UI (and also higher than that of the subsequent higher segments), See following table1: U PEC is called TGL (total (NIS) goitrogen load) here.

Table1: NHANES 2001-2002: Relationship between urinary iodine and TGL (sorted for iodine) [see PDF docket ID EPA-HQ-OW-2009-0297-0647]

Indeed, when applying the Tonacchera equation after converting molar concentrations into concentrations expressed in weight we have for women B with urinary iodine average of 228 ug/l (n=1109/8= 139) (See table 1 above, col.1):

RAIU-B i= 1.22 / (1.22 +PEC) where PEC = [ClO4-] + [SCN-] / 8.8 + [I-] / 38 + [NO3-] / 150)

= 1.22 / (1.22 + 5.9+2205/8.8+228/38+74567/150) =1.22/(1.22 +5.9+251+6+497)=1.22/(1.22+760) =1.22/761.22 =0.0016

And for women with iodine average of 31 ug/l (n=1109/8= 139) (see table 1 above, col.1).

RAIU-A = 1.22 / (1.22 +1.5+967/8.8+31/38+19293/150) = 1.22 / (1.22 +1.5+110+0.8+129) = 1.22 / 242 =0.005.

Thus RAIU-A is about 3 times larger than RAIU-B which means that the incremental iodine uptake inhibition for A women with urinary I =31 ug/l has to be less than for B women with I = 228 ug/l. This is due to the substantially higher total goitrogen load of women with the higher iodine level; see following tables 2, 3 and 4

Table 2, iodine insufficient women (<100ug/l UI): col. 9 : total goitrogen load(TGL) is about half and each of the 3 NIS goitrogens nitrate(col. 5), thiocyanate (SCN, col.7) and perchlorate (col.8) are about half of TGL for iodine sufficient women (>100ug/l UI, table 3) and for the total population (table 4)or in other words women with sufficient iodine have about double the NIS goitrogen load.[see PDF docket ID EPA-HQ-OW-2009-0297-0647]

Since, as mentioned, B women (228 ug/l UI) are not exposed to iodine uptake inhibition, A women (31 ug/l UI) should not be exposed to iodine uptake inhibition either and therefore TH levels could not be affected by the goitrogen load (of which perchlorate only represents 1%). In other words, since we can confidently assume that NIS goitrogen load does not affect iodine uptake in the NHANES 2001-2002 women with mean iodine levels of 228 ug/l urinary iodine it follows from above calculations that NIS goitrogen load, and a fortiori perchlorate load which only represents 1% of this load, does not affect iodine uptake and a fortiori TH levels in NHANES 2001-2002 women with the lowest iodine levels of only 31 ug/l. as a mean.

Conclusion

Based on the above analysis of goitrogen levels, iodine uptake and using the Tonacchera equation, it is not possible that the ability of urinary perchlorate to significantly predict TH changes in women with urinary iodine less than 100 ug/L reported by Blount et al., 2006, is directly associated with the joint goitrogen effect of nitrate, perchlorate and thiocyanate. Thus, it is not possible that the association is directly connected to perchlorate alone. More likely, the higher goitrogen load of iodine sufficient women is related to a healthier diet, one rich in vegetables and fruit.

Response: EPA cannot evaluate calculations that have not been peer reviewed.

Comment: EPA must also consider other exposure pathways and additional contaminants in the environment that impact thyroid function when establishing the MCL. Studies of perchlorate levels in food, including breast milk, show that the population is exposed through multiple pathways

in addition to contaminated drinking water. EPA should determine potential aggregate exposures based on a broad range of contamination levels, and not just the mean, which was the basis for current estimates. While data have also demonstrated a particular threat to the significant number of individuals, especially women of child bearing age, who are iodide deficient, the current modeling does not include this threat.

Given this widespread problem (CDC estimates up to 30% of women do not get sufficient dietary iodide), it is critical to take into consideration the potential for exposure to other thyroid-active agents. Consequently, EPA must consider the cumulative impact of perchlorate, other substances in the environment that inhibit the uptake of iodide by the thyroid, and inadequate supplies of iodide in American diets, all of which makes a stringent drinking water standard necessary to be truly health protective.

Response: EPA will consider a variety of sources of perchlorate in developing the NPDWR.
As demonstrated in the in the August 2009 Supplemental Request For Comments, breast fed infants is a group identified by EPA as of interest.

Comment: Other contaminants are known to also interfere with iodide uptake via a similar or identical mechanism. For example, the widespread water contaminant, nitrate has a shared mechanism of action as does the chemical thiocyanate, found in cigarette smoke and in some foods.[FN44: Ginsberg G and D Rice. The NAS perchlorate review: questions remain about the perchlorate RfD. Environ Health Perspect. 2005 Sept; 113(9):1117-9. Erratum in: Environ Health Perspect. 2005 Nov; 113(11):A732.] There is some indication in the CDC data analyzed by Blount et al. that nitrate may be a factor in the modulation of thyroid hormone status. An independent analysis by OEHHA staff found an interaction between perchlorate and thiocyanate exposure and tobacco smoke exposure on thyroid hormone. It is also known that perchlorate and thiocyanate are found in breast milk.[FN45: Kirk, AB, Dyke JV, Martin, CF, Dasgupta PK. 2007. Temporal patterns in perchlorate, thiocyanate, and iodide excretion in human milk. Envrion Health Perspect.115(2):182-6.]

Perchlorate: The Greer Non Observed Effect Level (NOEL) and the NAS Reference Dose (RfD) are significantly inaccurate and do not provide a defensible basis for regulation

By: Herwig Opdebeeck, SM, Opdebeeck Consulting

In its Perchlorate Supplemental Request for Comments, published in the Federal Register on August 19, 2009, EPA states that its preliminary regulatory determination will be based upon the RfD and risk assessment derived from the 2002 Greer study. However, as discussed below, the Greer NOEL did not take into account background effects, including the effects of other goitrogens, and is thus not a true NOEL. The true NOEL is the perchlorate dose administered in the Greer study (7 ug/kg-day), plus the dose corresponding to the background effect. The fact that this background level has not been added and is not taken into account, leads to a fundamental flaw in the perchlorate risk assessment and should not be relied upon to either regulate perchlorate or establish an RfD .

Response: EPA disagrees.

Commenter Name: Herwig Opdebeeck
Commenter Organization: Opdebeeck Consulting
EPA Document ID: EPA-HQ-OW-2009-0297-0227
EPA Comment ID: 28819
EPA Comment Code: 2600

Comment: Indeed, analyzing the NHANES database, we found that the perchlorate NOEL -- identified in the Greer study as the point at which the slightest decrease in iodine uptake occurs -- is not 7 ug /kg-day, but 157 ug /kg-day absent any perchlorate or perchlorate equivalent background level in the Greer cohort (which is assumed to be representative for the US population).

Second, and perhaps more significantly, even though the level of background perchlorate is low, other goitrogens in the environment represent a very significant perchlorate equivalent background, 22 times more potent than the Greer NOEL and more than 2,200 times more potent than the perchlorate background level itself for the general population (for women with insufficient iodine (<100 ug UI) the total goitrogen load and perchlorate background are about half, see study addendum 1. This should reflect on the goitrogen level in general and the perchlorate level in particular of foetuses and breast-fed neonates). This perchlorate equivalent background mostly consists of thiocyanate and nitrate in food and water.

Therefore, the true NOEL is the Greer apparent NOEL + the background perchlorate equivalent level (PEC) and is, at 157ug/kg-dayPEC, 22 times larger than the apparent Greer NOEL of 7 ug /kg-day. This leads to a PEC RfD of 15.7 ug/kg-day instead of the NAS RfD of 0.7 ug/kg-day.

This background level should be taken into account in evaluating whether regulation of perchlorate through the Safe Drinking Water Act would result in a meaningful opportunity for health risk reduction for persons served by public water systems, and in determining what constitutes a level of public health concern. For the reasons discussed below, regulation of perchlorate would not achieve either of these goals, because the effect on iodine uptake (the basis for the NOEL) resulting from perchlorate in public drinking water systems is inconsequential in comparison to the effect of other substances on iodine uptake. Due to the significant impact of these substances on iodine uptake,

even the elimination of perchlorate from the drinking water supply would result in (at best) only a negligible improvement in iodine uptake, and would have no effect on overall public health. If the purpose of the PHG is to be truly health protective, the perchlorate equivalent drinking-water PHG would need to be shared with those other goitrogens. For drinking-water, that would mean that the perchlorate PHG would need to be shared with the existing nitrate MCL.

Applying a default relative source contribution (RSC) of 20%, and assuming that the goal is to avoid the slightest iodine uptake inhibition caused by perchlorate and/or nitrate, we come to the conclusion that, even using the much higher NOEL level discussed above, to achieve the intended effect of the PHG, the MCL for nitrate would need to be drastically lowered (by more than 80 % if the perchlorate PHG were between 0 (zero) and 1 ppb and by more than 75% if the PHG were to be 15 ppb) and the vegetable and fruit intake of a large segment of the US population (all of the population with a balanced diet) would need to be limited to the daily consumption of fruit and vegetables equivalent to the nitrate content of 2.3 ounces of lettuce or equivalent to the thiocyanate + nitrate content of an even smaller amount of broccoli.

The logical conclusion of this analysis indicates that either the nitrate MCL is too high to avoid iodine uptake inhibition, or a NOEL based on iodine uptake inhibition is not an appropriate effect on which to base a PHG for perchlorate. Because foods containing nitrate and thiocyanate are an integral part of a healthy diet, and the effects on iodine uptake can be countered by adequate levels of iodine in the diet, logic dictates the latter conclusion.

This logical conclusion is further supported (if support would still be needed) by the fact that, as mentioned before; i) for women with insufficient iodine (<100 ug UI) the total goitrogen load and perchlorate background are about half, see study addendum 1; ii) according to the same NHANES database, urinary iodine is strongly and positively associated with urinary perchlorate which means that the more there is perchlorate background exposure the more there is background iodine exposure (see study addendum 2).

Response: See response to comment IDs 28529, 28551, and 20523 under comment code 2500 EPA cannot evaluate calculations that have not been peer reviewed. EPA believes the nitrate NPDWR appropriately derived.

Comment: 1.2. Determination of the background adjustment factor, BAF

1.2.1. Epidemiological studies: Quantitative Observational Study versus Experimental Study

In order to arrive at an RfD, an effect level is normally determined. The effect level is determined by means of epidemiological studies. By far the most common type of human epidemiological study is the quantitative observational study, which is one of the two that leads to dose-response information [FN3: R.L. Calderon ,The Epidemiology of Chemical Contaminants of drinking Water , US EPA, Food and Chemical Toxicology, 38, 2000.] (and which cannot be controlled for substances that have

not been measured). The other type is the controlled experimental study and is typically used to evaluate drugs or vaccines, but is seldom used to evaluate environmental contaminants.[FN3: R.L. Calderon ,The Epidemiology of Chemical Contaminants of drinking Water , US EPA, Food and Chemical Toxicology, 38, 2000.]

The quantitative observational study is in fact a dose-response study of the background level of the contaminant (which in the case of perchlorate is assumed to be food and drinking water). This is not the case of an experimental study, where the dose-response of the administered dose is studied and not that of the background level. This type of study instead presumes that the background level of the substance is zero, and that the only cause of the effect of the substance in the bodies of the subjects is the administered dose of the substance.

Therefore, in an experimental study such as the Greer study, the effect level that would be found through such longitudinal experiment would not be the true effect level. Instead, the true effect level would be the sum of the administered dose and the background effect level. The Greer 2002 study from which the RfD was derived was such an experimental study, and the background perchlorate exposure level may have been confused with the administered dose or may simply have been overlooked. Indeed, experimental clinical studies on humans are, for obvious reasons, seldom done in order to estimate the dose- response of environmental contaminants. The Greer 2002 trial, however, had as its endpoint a Non Observable Effect Level, which was considered a non adverse effect level. This trial was, therefore, an inappropriate method to effectively determine the NOEL.

1.2.2. NIS Iodine uptake inhibitors have a cumulative effect

Normally the (adverse) effect level of each contaminant is established independently from other contaminants, as most toxins have a specific effect, their effect is not cumulative at all levels, or their cumulative effect is simply not well known. However, this is not the case for the NIS competitive iodine uptake inhibitors, or goitrogens, whose mode of action is well known and is known to be cumulative. Particularly for the three major goitrogens-- nitrate, perchlorate and thiocyanate -- their simple cumulative effect and their relative potency are well known. Thus, in the case of the Greer study, the background level is the perchlorate background level, plus the level of other goitrogens with the same mode of action, i.e. the (competitive) inhibition of iodine uptake.

1.2.3. The Background Adjustment Factor BAF

Indeed, the Greer participants did have additional perchlorate doses through background food and drinking water perchlorate as well as background perchlorate equivalent caused by other goitrogens. This means that the NOEL from the Greer experimental study and which we call Greer_NOEL is lower than the real NOEL which we call PEC_NOEL (Perchlorate Equivalent Concentration NOEL) with PEC_NOEL = Greer_NOEL x BAF (Background Adjustment Factor) and with BAF>1.

1.2.3.1. The perchlorate background adjustment

The median perchlorate background exposure in the US adult population is 4.6ug/day,[FN4: Blount BC, Valentin-Blasini L, Osterloh JD, Mauldin JP, Pirkle JL, 2006a. Perchlorate Exposure of the U.S. Population, 2001-2002. Journal of Exposure Science and Environmental Epidemiology, 1-8.] which is 0.066 ug/kg-day representing only 0.9 % of Greer- NOEL. Thus the mean total perchlorate

exposure of the Greer cohort = 7 ug/kg-day + 0.066 ug/kg-day = 7.07 ug/kg-day which for all practical purposes we round off and keep at 7 ug/kg-day.

It is worth noting here that the cross-sectional Blount et al, 2006 background study [FN5: Blount BC, Pirkle JL, Osterloh JD, Valentin-Blasini L, Caldwell L, 2006b. Urinary Perchlorate and Thyroid Hormone Levels in Adolescent and Adult Men and Women Living in the United States. Environmental Health Perspectives 114(12): 1865-1871.] showed a weak but statistically significant relationship of this very low background exposure with an effect, and even more surprisingly a downstream adverse effect only. This same significant adverse effect relationship, however, is also shown to exist with the background level of some organo halogens in the same NHANES database but which are known, contrary to perchlorate, to cause that kind of weak adverse effect at such low levels.

1.2.3.2. Other goitrogen background adjustment

In addition, the Greer trial participants were exposed to a perchlorate equivalent background in food and drinking-water from the goitrogens thiocyanate (SCN), nitrate (NO3-) and other goitrogens affecting iodine uptake into the NIS such as fluoride, chlorate and several others. For practical purposes we will only take nitrate and thiocyanate into account as those two are the most important and best documented goitrogens (Michael Zimmermann, European Thyroid Association (ETA) Symposium, Lisbon, September 9, 2009).

In the US adult population, serum background exposure to nitrate expressed in serum perchlorate equivalent concentration (SPEC) is estimated at 0.167umol/l and that of thiocyanate at 1.333umol/l for a total of 1.567umol/l compared to a serum Greer_NOEL for perchlorate estimated at 0.070umol/l.[FN6: See Office of Inspector General Scientific Analysis of Perchlorate ,Assignment No. 2008-0010, December 30, 2008, page 84 and 85 (goitrogen serum and urinary levels based on the NHANES 2001-2002 dataset).] Thus, perchlorate serum exposure of 0.070 umol/L at the Greer NOEL dose represents only 4.5 % of the total serum goitrogen load of 1.567umol/L or in other words the perchlorate equivalent concentration NOEL, PEC_NOEL, which is the real NOEL, is 22.4 times larger than the Greer_NOEL(which itself is more than 100 times larger than the perchlorate background). PEC_NOEL = Greer_NOEL x BAF= Gr_NOEL x 22.4 = 157 ug /kg-day where BAF is a perchlorate equivalent BAF.

The Greer NOEL of 7ug/kg-day is not a true NOEL but a NOEL on top of the much larger (i.e. 21 times larger) perchlorate equivalent background level. Therefore, the true NOEL is the Greer apparent NOEL, plus the background equivalent perchlorate level, and is more than 22 times larger than the apparent Greer NOEL of 7 ug /kg-day. The background exposure level of perchlorate itself, however, is negligible as it is more than 100 times smaller than the Greer NOEL or more than 2,200 times smaller than the true NOEL, taking into account only the most well-known goitrogens.

1.2.4. The true reference dose RfD

The true RfD is obtained by dividing the true NOEL by UF (uncertainty factor) which NAS set at 10. Thus the true RfD or PEC_RfD = PEC_NOEL/UF = 157ug/kg-day /10 = 15.7ug/kg-day, equivalent with the ingestion of 2 litres of 550 ppb perchlorate drinking-water if there were no other goitrogen exposure from drinking-water, food and any other source.

1.2.5. From the true RfD to Perchlorate Equivalent Concentration PHG

To derive a PHG (Public Health Goal) or MCL (Maximum allowed Contaminant Level) for drinking-water from an RfD, usually a RSC (Relative Source Contribution) is applied.

Assume that 80% of perchlorate + nitrate + thiocyanate background originate from food and 20% from drinking-water. A 20 % RSC is the lowest and most conservative RSC used in the derivation of a maximum contaminant level goal [FN7: Regulatory Determination Support Document for selected Contaminants from the second Drinking Water Contaminant Candidate List (CCL-2), US-EPA report 815-D-06-007, December 2006.]. It is the minimum default value.

If no other goitrogens were present in drinking-water, the PHG would then be: 15.7 ug/kg-day x 70kg/2Lx 0.20= 110 ppb or again 22 times the 5 ppb proposed by for example NJ Department of the Environment which used the same 20 %RSC [FN8: http://www.nj.gov/dep/watersupply/perchlorate_mcl_10_7_05.pdf].

1.2.6. The perchlorate-only PHG in relation to the total perchlorate-equivalent PHG

If other goitrogens are present, a PEC_PHG (i.e. the total perchlorate equivalent PHG) should be shared with those other goitrogens. This approach is the only sensible approach, as no distinction between the goitrogens can be made if the goal of the MCL is to be health protective.

For drinking water, nitrate would be the most significant other goitrogen. If the current nitrate MCL were taken into consideration, then PEC_PHG should be equal to PHG of perchlorate + MCL of nitrate expressed in PEC (Perchlorate Equivalent Concentration)[FN9: Nitrate PEC = [nitrate]/240 when expressed in molar weight and /150 when expressed in weight: De Groef B, Decallonne BR, Van der Geyten S, Darras VM, Bouillon R, 2006. Perchlorate Versus Other Environmental Sodium/iodide Symporter Inhibitors: Potential Thyroid-related Health Effects. Eur J Endocrinol 155(1):17-25.].

As mentioned, the combined perchlorate + equivalent nitrate maximum level should be< 110 ppb or ([Nitrate] PEC+ [perchlorate] should be <110 ppb. Since the nitrate MCL = 44 ppm nitrate or 44,000/150ppb=293 ppb PEC, PE_PHG should be equal to PHG perchlorate + 293ppb. Hence, PHG perchlorate should be equal to 110 ppb-293 ppb= negative 183 ppb, which is of course not possible.[FN10: Note: if an RSC =1, as was the case for the nitrate MCL, would have been applied on the background perchlorate equivalent level as well, PEC_PHG would have been = (15.4 ug/kg-day) x 70kg/2 l x 1= 539 ppb. Indeed in determining the drinking water nitrate MCL no RSC (i.e. RSC=1) taking into account food has been applied even though nitrate levels in food such as vegetables are very significant (and as much significant in terms of BBS as iodine uptake inhibition).If this would have been done, it would on itself already have lowered substantially the nitrate MCL. A 0.2 default value, as we apply here for PEC, would have lowered it already to 8.8 ppm. According to the WHO (see ref. 12) the contribution of drinking-water to nitrate intake is usually less than 14 so even lower than the conservative 20 % default value assumed here.]

Thus, we must conclude that either the nitrate MCL is too high to avoid iodine uptake inhibition, or a NOEL based on iodine uptake inhibition is not an appropriate effect on which to base a PHG for perchlorate -- or both. If, nevertheless, the iodine uptake inhibition NOEL is to be kept as the

relevant effect, the nitrate MCL should be lowered in the first instance from 44 to 14.2 ppm to allow a perchlorate PHG of for example 15 ppb, the one EPA currently proposes as an interim level.

There is an additional background adjustment, another RSC, to be made for nitrate. Contrary to perchlorate and thiocyanate for which the serum exposure is proportional to the oral exposure, there is, besides an oral exposure, also an endogenous exposure to nitrate estimated at 45% of total nitrate exposure.[FN11: Nitrate and Nitrite in Drinking Water, Subcommittee on Nitrate and Nitrite in Drinking Water, Commission on Life Sciences, NRC (National Research Council), page 38. Washington, DC, National Academy Press, (ISBN-10: 0-309-08370-2).] Therefore there is an estimated relative source contribution of exogenous (oral) nitrate of 55% only. Thus to allow a perchlorate PHG of 15 ppb the nitrate MCL should be further lowered to 14.2 x 0.55= 7.8 ppm nitrate (or 2.1 ppm N as nitrate instead of 10 ppm N as nitrate) or about 1/5 of the current MCL). (This cannot be significantly compensated for by further lowering the perchlorate PHG from 15 to 1ppb (a 93% decrease), since this would only allow an increase of the nitrate MCL from 7.8 ppm to a still very low 9.9 ppm(a 27% increase only), still ending up with less than 1/4 of the MCL).

So, even with a PEC of 110 ppb (based on a true RfD of 15.5ug/kg-day PEC and a RSC of 20%), it is obvious that either the nitrate MCL (=293 ppb PEC) is too high to avoid iodine uptake inhibition or a NOEL based on iodine uptake inhibition is not an effect on which to base a PHG for perchlorate, or both.

Further, since we used a 20% default RSC which resulted in a perchlorate + nitrate MCL of 110 ppb for drinking-water, this means that the perchlorate equivalent exposure through drinking-water would be 2 Lx 110 ug/lL = 220 ug per adult /day. This would also mean that the intake through food, which would represent 80%, would be 220x80/20= 880 ug per adult/day perchlorate equivalent. This seems high on first sight but in reality is not as it represents an ingestion of only 66 g (2.3 ounce) of lettuce containing an ordinary 2000 ppm nitrate [FN12: Nitrate and nitrite in Drinking-water, Background document for development of WHO Guidelines for Drinking- water Quality, Originally published in Guidelines for drinking-water quality, 2nd ed. Addendum to Vol. 2 Health criteria and other supporting information. Word Health Organization, Geneva, 1998.]; (Hydroponic lettuce can contain up to 6000 ppm (40,000 ppb PEC) nitrate) or an even lower amount of broccoli (broccoli contains a mean of 11,500 PEC nitrate and 2000 PEC thiocyanate).[FN13: Perchlorate, Thiocyanate, and Nitrate in Edible Cole Crops (Brassica sp.) Produced in the Lower Colorado River Region, C. A. Sanchez, B. C. Blount, L. Valentin-Blasini,R. I. Krieger, Published online: 26 October 2007, Springer Science + Business Media, LLC 2007.]

Further, this also means that if the [perchlorate + nitrate] MCL were only 110 ppb PEC, consuming 66 g /day of lettuce and 2 litres of 110 ppb PEC DW would already represent the maximum allowed daily dose though water and food and no other nitrate carriers such as spinach, melon, cured meats and thiocyanate carriers such as broccoli and cauliflower, (which in themselves cause an average 8 times higher exposure load than nitrate)[FN14: Office of Inspector General, Scientific Analysis of Perchlorate, Assignment No. 2008-0010, December 30, 2008.] could be consumed that day by a healthy adult. Besides that, the nitrate level of the water consumed the same day could not exceed 1/5 of the current MCL if a perchlorate PHG of only 15 ppb would be chosen and 1/4 if a perchlorate PHG of 1 ppb would be chosen, as shown above.

Since in the US about half of the groundwater exceeds 10 ppm perchlorate and 6 % of groundwater exceeds 20 ppm[FN15: See ref. 12.] and almost all DW exceeds 1/5 of the MCL, the conclusion

should be that if a 15ppb or lower MCL for perchlorate is determined, the US population should basically stop consuming drinking water derived from groundwater and vegetables and fruit containing thiocyanates and nitrates. Even bottled water would not help much as almost all contain more than 5 ppm nitrate (based on a quick supermarket inquiry by the author) or 33 ppb PEC. Even "pristine", expensive imported bottled water contains between 3 and 10 ppm nitrate or up to 66 ppb perchlorate equivalent.

Conclusion

The NAS RfD, derived from the Greer NOEL is not a true RfD, since the Greer NOEL does not include the perchlorate equivalent background. The true RfD, at 15.5ug/kg-day, is more than 22 times larger than the NAS RfD of 0.7ug/kg-day.

Even at this higher RfD, however, the impact of other goitrogens, such as nitrate, in drinking water and food and thiocyanate in food would make it impossible for any level of perchlorate regulation to have any meaningful impact on public health. One reason for this may be that the appropriate "effect" to be considered in the evaluation of a NOEL should not be the point of iodine uptake inhibition, since the contribution of nitrate and even more of other goitrogens such as thiocyanate already largely exceeds the level of iodine uptake inhibition in healthy diets. Based on the foregoing, EPA is unable to demonstrate two of the three criteria required to regulate perchlorate in drinking water - namely: (1) EPA cannot demonstrate that perchlorate will occur in public water systems at levels of public health concern, because it cannot accurately be determined what constitutes a level of public health concern based on the current studies, and (2) EPA is unable to demonstrate that regulation of perchlorate represents a meaningful opportunity for health risk reduction for persons served by the public water system, since even its elimination would not result in any meaningful improvement in public health.

Comment: ADDENDUM 1

By: Herwig Opdebeeck, SM, Opdebeeck Consulting

The unexpectedly weak goitrogen load of the iodine-deficient female US population

The U.S. iodine insufficient female population, besides an inadequate iodine containing diet, seems to have a generally unbalanced diet characterised by a low consumption of vegetables.

We refer again to the NHANES 2001-2002 data on urinary perchlorate (CLO4), nitrate (NO3), thiocyanate (SCN) and iodine where we show the relationship between iodine and total goitrogen load (TGL).

Table 1, 2, 3: NHANES 2001-2002: Relationship between iodine and total goitrogen load (TGL) (sorted for T4) [see PDF docket ID EPA-HQ-OW-2009-0297-0227]

The first table is for women with <100 ug/l urinary iodine (women<100), n=384), the second for women with >100 ug/l urinary iodine (women>100, n= 725), the third for the total population (n=2080) (Individuals with >2000 ug/l urinary iodine have been removed).

From these tables the following observations can be made:

Preliminary note: The serum goitrogen load is a measure for the effective thyroid goitrogen load. Here we refer to the urinary (U) load which does not accurately reflect the effective serum load. For example the residence time of thiocyanate is much longer than the one of nitrate or perchlorate. However this does not matter here since the purpose is only to compare the urinary loads between the different population groups i.e. the relative loads and because we can assume that urinary loads are proportional to serum loads (for example a double urinary load also means a double serum load).

-Women with iodine levels < 100 have a total goitrogen load(TGL) expressed in PEC that is about 50% lower than women > 100 and than the overall population (columns 9).

-Split into the constituents, their perchlorate, nitrate and thiocyanate levels, over the entire T4 spectrum (Col. 2), are about 50%, 50% and 35% lower respectively (columns 8, 5 and 7).

- This means that women with insufficient iodine levels happen to be those that are least susceptible to iodine uptake inhibition, if they would have been iodine sufficient.

-Urinary(U) perchlorate for all population groups represents less than 1% of the total urinary goitrogen load expressed in PEC (columns 10) and, as shown in section 1 above, also of the total serum(S) load.

Conclusion

Women with insufficient iodine levels happen to be those that are least susceptible to iodine uptake inhibition, if they would have been iodine sufficient. Improving their diet and iodine uptake would be the remedy.

Lowering instead the perchlorate intake by any rate (1, 10 or 100%) would not diminish NIS iodine uptake inhibition, also not for iodine-insufficient (<100) women since the NIS iodine uptake inhibition potential caused by TGL which is more than 100 times larger, is already 50 % lower than for iodine sufficient women (>100). So besides the fact that eliminating all perchlorate even the background level would still leave 99% of TGL untouched, this remaining 99% is only half that of iodine sufficient women.

ADDENDUM 2

By: Herwig Opdebeeck, SM, Opdebeeck Consulting

The strong relationship of low levels of U-perchlorate with U-iodine levels

In continuation of Addendum 1 : Nevertheless women with urinary iodine < 100 ug/l have a ratio of iodine to total goitrogen load (TGL) equal to about 0.2/1 for every T4 octille (1/8) while women > 100 ug/l have about a ratio equal to 0.8/1 also for every T4 octille (columns 13 of above 2 first tables of addendum 1) which means that, even though the goitrogen load for iodine-insufficient women is only about half that for iodine sufficient women, their iodine inhibition potential is 4 times higher so it is obvious that if iodine uptake inhibition in this subpopulation would occur it would be due to lack of iodine and not due to goitrogen load.

For perchlorate this is even more explicit since perchlorate, at low levels, is strongly related to iodine: see next figure[FN16: 1. Charnley G, Perchlorate: Overview of Risks and Regulation. Food and Chemical Toxicology, 2008. 2. Soldin OP, Tractenberg RE, Pezzullo JC. Do thyroxine and thyroid-stimulating hormone levels reflect urinary iodine concentrations? Therapeutic Drug Monitoring. 2005, 27: 178-185.] (fig.2) which is derived from the same NHANES 2001-2002 survey.

Fig 2 Relationship between urinary iodine and urinary perchlorate for the general population controlled for gender, T4 and TSH, p<0.0001 (ug/l, log scale) [see PDF docket ID EPA-HQ-OW-2009-0297-0227]

This relationship also suggests that low levels of perchlorate are naturally linked to iodine (both are formed in the atmosphere and both are found in naturally nitrate -rich soils in the US S-W deserts and arid regions).

So women with low natural background levels of perchlorate have low natural background levels of iodine. For higher background levels of perchlorate the link with iodine ceases to exist or not enough data points exist for those higher levels.

Thus it seems that women with higher levels of iodine not only tend to have higher levels of natural perchlorate but additionally some from other contaminated (point) sources.

For the other 2 goitrogens this suggests that those iodine-insufficient women also consume significantly less vegetables than the iodine-sufficient population. This could then also explain the higher non-natural levels of perchlorate from vegetables irrigated with synthetic perchlorate containing water such as the Colorado River (or, as mentioned before, this non- relationship can be due to a lack of data points at those higher levels). Nevertheless those synthetic perchlorate levels are themselves still insignificant compared to the total goitrogen load.

All this strengthens once more the argument that in the US population the potential iodine uptake inhibition does not lay with goitrogens and even less with perchlorate but clearly with a lack of iodine.

Conclusion - Even though the goitrogen load of iodine insufficient women is only about half that of goitrogen sufficient women, their ratio iodine to goitrogen load is much lower which suggests once again that the remedy is iodine. - For low background levels of perchlorate there seems to exist a remarkable relationship with iodine which suggest that those lower levels are natural levels since synthetic perchlorate such as rocket fuel does not contain iodine. - It is once again suggested here that Iodine insufficient women seem to have also a diet low in vegetables besides a diet low in iodine containing food such as fish.

Comment: Fifth, the level of IUI that would be associated with exposure to perchlorate at the RfD is minimal compared to the IUI associated with other environmental goitrogens naturally present in many foods. Nitrate and thiocyanate are less potent (Tonacchera et al., 2004) but more plentiful inhibitors of NIS activity than perchlorate (Belzer et al., 2004). The potency of nitrate and thiocyanate relative to perchlorate has been demonstrated in vivo (Wyngaarden et al., 1952, 1953; Greer et al., 1966; Belzer et al., 2004) and in vitro (Tonacchera et al., 2004). When based on perchlorate equivalence, the effects of perchlorate are much smaller than the effects of either nitrate or thiocyanate (Belzer et al., 2004; U.S. EPA, 2008b). The potential for perchlorate to inhibit iodide uptake cannot be distinguished from the effects of other NIS inhibitors (De Groef et al., 2006). Because exposure to nitrate and thiocyanate would continue, the premise underlying EPA's attempt to isolate the effect of perchlorate is limited in its ability to provide an actual public health benefit.

Comment: One major scientific issue is that the effects of agents that affect IUI in the same way as perchlorate were not considered by the Notice.

Because perchlorate, nitrate, and thiocyanate compete with iodine for uptake by the NIS, the combination of these chemicals in food or water will affect iodine uptake to the thyroid as well as absorption into the body from the gut. The NIS is located in the small intestine and uptake of iodine can be reduced by sufficient doses of perchlorate (Brown-Grant, 1961). In defining a HRL, it is assumed that 100% of an ingested dose is able to reach the thyroid. Of the four chemicals (perchlorate, nitrate, thiocyanate, iodine), perchlorate has the highest affinity for the NIS, however, the other three are more abundant in the diet. In the FDA Total Diet Study, the dose range of perchlorate was 2.4 to 9.1 ug/person-d and the dose range of iodine was 144 to 353 ug/person-d (Murray et al., 2008). Similar to biomonitoring studies (Blount et al., 2006) and dose models (Belzer et al., 2004), the OIG Draft Report (U.S. EPA, 2008b the results for exposures to nitrate, thiocyanate, and perchlorate found that perchlorate accounted for less than 1% of the predicted IUI in the total goitrogen load. Based on NHANES 2001-2002, the average urinary concentration of perchlorate was 4.8 ug/L, which was much lower than the urinary concentrations of nitrate, thiocyanate, and iodine at 55,017 ug/L, 2,042 ug/L, and 200 ug/L, respectively. Figure 2 demonstrates the relative contribution of perchlorate to total goitrogen load using another set of data, the NHANES 2001-2002 database.

Figure 2. Total goitrogen load in perchlorate equivalence* based on urinary measurements from women ages 12 and older from NHANES 2001-2002.** [see PDF docket ID EPA-HQ-OW-2009-0297-0662]

One characteristic of this relationship is that as perchlorate dose increases in food, so does intake of nitrate, thiocyanate, and iodine. Figure 2 presents the cumulative intake of the four agents based on NHANES data using perchlorate equivalence of the urinary concentration of nitrate and thiocyanate. Two things become clear. First, as iodine level increases, so does total cumulative dose. Second, perchlorate contributes, by far, the smallest amount to total cumulative dose. The chart shows that as the goitrogen load increases, people tend to have increased intake of iodine, probably due to greater ingestion of total food.

EPA Comment ID: 28928
EPA Comment Code: 2600

Comment: Background: Perchlorate is unique among chemical contaminants for its ubiquity- it has been found as a contaminant in drinking water in at least 26 states, in 74% of nearly 300 types of commonly consumed foods and beverages tested by the Food and Drug Administration (FDA), and in the urine of 100% of Americans tested by the Centers for Disease Control and Prevention (CDC) (GAO 2005, Blount et al 2006a, Murray et al 2008). Its primary clinical effects are on the thyroid gland, where it can disrupt the production of thyroid hormones that are critical for normal brain development and growth in the fetus, infants, and children. Perchlorate inhibits thyroid hormone synthesis by preventing iodine, the building block for thyroid hormones, from being taken up into the thyroid gland from the circulation. Iodine status is especially important in determining vulnerability to perchlorate, as confirmed by a recent large-scale epidemiological study from the CDC that found that women with lower iodine levels had more significant changes in thyroid hormone levels associated with environmental perchlorate exposure when compared with women with higher iodine levels (Blount et al 2006a).

Response: EPA agrees that individuals with inadequate iodide nutritional status are more likely to be adversely impacted by perchlorate.

EPA Comment Code: 3000

Comment: Other Considerations

AMWA believes that factors other than those discussed in the notice need to be considered. The contamination of water supplies by perchlorate is on-going and spreading unlike many other CCL contaminants where a determination not to regulate has been made, such as in the case of pesticides that are no longer used and have low and decreasing occurrence levels. Perchlorate, on the other hand, is expected to have increasing occurrence levels and impact increasing numbers of water systems - clearly a call for at least the actions outlined herein.

AMWA appreciates the opportunity to comment on EPA's preliminary regulatory determination. If EPA has any question about our comments please do not hesitate to contact me or Erica Brown, Director of Regulatory Affairs, at 202-331-2820.

Sincerely,

Diane VanDe Hei Executive Director Cc: Cynthia Dougherty, OGWDW Eric Burneson, OGWDW

Response: EPA has determined to regulate perchlorate in drinking water. See response to comment code 6120. Regarding perchlorate contamination of water supplies, EPA acknowledges that some systems may have had an increase in perchlorate occurrence. The Agency analyzed the additional information and decided that regulation of perchlorate due to occurrence and health implications was warranted.

EPA Document ID: EPA-HQ-OW-2009-0297-0528
EPA Comment ID: 28512
EPA Comment Code: 3000

Comment: Perchlorate has been found in over 400 drinking water sources in 26 states, potentially affecting tens of millions of people. EPA's own data say that nearly 17 million people receive their water from public water systems where perchlorate has been found at levels exceeding 4 ppb. Were sampling routinely conducted with a detection limit of 1 ppb, that number would be much higher- particularly considering the estimated 20 million people in the Southwest who receive drinking water from the Colorado River.

Response: EPA estimates that at least 5.1 to 16.6 million people are served by PWSs, for which we have data, that have perchlorate contamination. EPA has determined that a NPDWR for perchlorate could reduce perchlorate exposures for these populations to levels below the potential alternative HRLs that EPA has identified as levels of public health concerns for purposes of this determination, and that such exposure reductions present a meaningful opportunity for the reduction of health risks for persons served by PWSs.

EPA Comment ID: 28747
EPA Comment Code: 3000

Comment: 4. The collection of new data for perchlorate in public water systems would provide reliable occurrence data to inform the establishment of a national primary drinking water standard. The need for new occurrence data is underscored by the significant improvements in water quality (considerably lower perchlorate concentrations) within the Lower Colorado River System since the UCMR 1 data were collected between 2001 and 2005. Additionally, newer and more sensitive analytical methods are now available that would permit perchlorate analysis with reporting limits (detection limits) at or below 1 ug/L. Consequently, the new occurrence data would represent a more robust data set that would permit statistical analysis without the inherent limitations present in the current Bayesian modeling of the existing, outdated occurrence data.

Response: EPA acknowledges that there are newer and more sensitive analytical methods that are now available that would permit perchlorate analysis with reporting limits at or below 1 ug/L. The Agency does not believe that additional monitoring data is needed to determine that perchlorate meets SDWA's criteria for regulating a contaminant. EPA's UCMR data is nationally representative and sufficient for estimating the frequency and level of perchlorate contamination. In addition, the Agency plans to further evaluate perchlorate occurrence as part of the proposed national primary drinking water regulation.

Commenter Name: Tom Porta
Commenter Organization: Nevada Division of Environmental Protection (NDEP)
EPA Document ID: EPA-HQ-OW-2009-0297-0638
EPA Comment ID: 28754
EPA Comment Code: 3000

Comment: Comment C.4.a.2: The NDEP recommends EPA require collection of new occurrence data to support the latter two of the three criteria that EPA most demonstrate in order to regulate this contaminant in drinking water; namely: (1) the contaminant is known to occur (or there is a substantial likelihood that the contaminant will occur) in public water systems, with a frequency and at levels of public health concern; and (2) regulation of such a contaminant presents a meaningful opportunity for health risk reduction for persons served by public water systems. The existing occurrence data are both outdated and nonrepresentative of current conditions.

The Unregulated Contaminant Monitoring Program is designed to collect such data for use in evaluating and prioritizing contaminants on the Drinking Water Contaminant Candidate List. It is an established program to "help ensure that future decisions on drinking water standards are based on sound science" (www.epa.gov/safewater/ucmr/ucmr1/factsheet.html#list). Perchlorate was on the analysis list published for the first Unregulated Contaminant Monitoring Rule (UCMR 1) in 1999 to collect data from 2,800 large public water systems and 800 small public water systems throughout the United States, but as further discussed elsewhere herein, the data is now largely obsolete due to analytical method changes and perchlorate remediation work in the Southwest. The NDEP recommends that EPA consider use of the established and successful UCMR process to collect updated national public water system occurrence data.
